A STUDY OF URETERAL IMPLANTATION

WITH A DESCRIPTION OF A NEW PROCEDURE*

A PRELIMINARY REPORT

THOMAS J. KIRWIN, M.D.

NEW YORK

THE study of congenital anomalies has always exercised a great fascination over both lay minds and medical. Until the age of Roentgen most of these were the findings of the autopsy table, and thus exercised but little influence upon medicine or surgery clinically applied. A conspicuous exception to this was ectopia vesicae, exstrophy of the bladder. This greeted the astonished gaze of the ancient Egyptian accoucheur and caused consternation to the Renaissance midwives whose patients numbered among them the consorts of kings. The occurrence of this congenital malformation has been noted ever since medical history began to be written. Naturally therefore, it is also the one toward which the earliest attempts to afford relief of its most distressing consequences have been directed. During a long period these efforts were confined solely to attempts to draw the gaping pubic bones together, or in some other way to supply an anterior wall to the bladder. The effort seldom succeeded and even if it did, the paramount problem of urinary incontinence still remained. Though it had long been known that in reptiles and birds a single duct serves to convey both urine and feces from the body, and that very early in human embryonic life one excretory tract serves

all purposes, it was not until the middle of the nineteenth century that the possibility of treating bladder exstrophy by artificial reproduction of this condition was perceived. At this time the history of ureteral transplantation may be said to have begun.

CHRONOLOGY OF ATTEMPTS TO IMPLANT THE URETERS IN THE LOWER BOWEL

The history of uretero-intestinal anastomosis has been presented more or less completely by a number of authors. The first complete monograph on the subject appears to be that of Peterson, which brings the subject down to the beginning of the present century. Steinke in 1909 and Buchanan at almost the same time presented less elaborate but nevertheless complete historical summaries. From time to time thereafter the subject was reviewed under studies of exstrophy of the bladder, the most notable of these being C. H. Mayo's contribution to the Osler Anniversary volume; Stevens in 1916 and the Hutchins brothers in 1923 also reported cases of ureteral transplantation for bladder exstrophy and gave summaries of literature. The historical material which follows has been largely gathered from the sources just mentioned, though in case of doubt or disagreement, recourse

* From The Department of Surgery, Yale University. An essay presented to the Faculty of the Graduate School of Yale University in candidacy for the degree of Master of Science, 1929. Submitted for publication October 10, 1929.

has been had to original sources in so far as they are available.

Anastomosis between ureter and bowel was preceded by the attempt to establish a ureterorectal fistula. The surgical procedure known during the seventeenth and eighteenth centuries as "cutting for the stone" and still popular until within the memories of those who are still with us in extreme old age, not infrequently left intractable fistulae between organs adjacent to the site of operation. It had been noted in certain cases where the rectum and urinary apparatus were thus placed in communication that it was possible for the patient to control the urine which leaked into the rectum by means of the anal sphincter, and that the rectal mucosa seemed to be tolerant of the presence of urine. The procedure carried out by Lloyd, October 3, 1851, was an attempt to establish an opening from the bladder into the rectum. It was the first step in an operation which was to have included closure of the open bladder by some sort of plastic repair. The wall of the rectum and the adjacent bladder wall, bearing the ureteral orifices, were both pierced by a needle, carrying a thread to which a skein consisting of numerous threads was attached. This "wick" was left in place by the withdrawal of the needle, and it was hoped that the outpourings of both ureters would pass down by it to the rectum. Unfortunately the patient was carried off on the seventh day by peritonitis. The anomalous condition had extended to the placement of the peritoneum, which was found to have descended so much lower than the surgeon had any reason for expecting that the needle had been passed *through* instead of beneath it.

In reporting Lloyd's fatality, mention is made of a case then in the hands of Sir John Simon, which was "of an analogous description." Simon's operation was actually done before Lloyd's (July 5 of the same year) and was more nearly a genuine anastomosis, even though the fistula idea was still followed out. "Instru-

ments of a very ingenious construction were contrived" for Simon, by means of which he was able to pass threads from ureters to rectum. Traction upon these threads induced pressure necrosis and eventually uretero rectal fistulae. Some twenty days later most of the urine was flowing into the rectum and in the course of three months the operator sought to close up the natural ureteral openings and protect the exposed bladder. His efforts were not crowned with success; the patient went down hill steadily and died "of exhaustion" in about a year. Autopsy showed great disorganization of the urinary apparatus due to "suppurative inflammation." In view of the conditions already existing, in all probability, before the operation was undertaken, and the state of urological knowledge at that period, the fact that the patient survived as long as he did certainly reflects no little credit on the attending surgeon.

The first actual transplantation of the ureters was done by Thomas Smith in 1878, though even here the fistula principle still prevailed. A left lumbar incision was made; the left ureter was located by the passage of a bougie cut off as low as possible, and carried into the descending colon through a small incision. A suture of fine carbolyzed catgut was passed through the bowel wall and the cellular tissue of the ureter, holding the anastomosis in place. The urine from the left ureter passed with the feces for six days, none passing through the "artificial anus." Thereafter the child developed fever, both urine and feces passed at the lumbar incision and there was abscess formation in the loin about the kidney. After a month the situation cleared up, the child improved in health and was "up about the ward." When a year had elapsed since the closing of the abscess fistula it was deemed wise to repeat the intervention on the right side, which Smith expected to find much easier, as the parts involved would be more accessible. There was, of course, no means of testing the condition of the left kidney.

The second operation was done; within fifty hours the child had died of uremia. Inflammation subsequent to surgical handling had inhibited the working of the right kidney, which, "very much enlarged," had been carrying on the work of both sides. Ascending infection had long before destroyed all the secreting tissue of the left kidney. Smith's conclusions were that anastomosis between the ureters and the bowel was perfectly feasible; that the lower intestine was perfectly tolerant of the presence of urine in its content; but ureteral transplantation would never be possible because any communication between ureter and bowel was, in itself, a fatal lesion.

Smith's pessimism did not permanently, at any rate, deter others from repeating the attempt. In 1891 Küster removed a carcinomatous bladder and transplanted both ureters into the rectum. The patient succumbed in five days to peritonitis and renal infection. In 1892 Chaput did two operations along similar lines. The first was upon a woman suffering from ureterovaginal fistula. The ureter was doubly sutured to the rectum, one set being stitched through the mucous membrane and the other through the serous coats. Peterson communicated with the French surgeon eight years after this operation was performed and found that the patient was in good health, though no details were obtained as to the actual condition of the kidney. No conclusions can be drawn from a unilateral case under these circumstances. Chaput's second patient was not so fortunate. Upon her he did a double implantation of the ureters into the colon and cecum, three months intervening between the two steps of the operation. From the first intervention the patient made a rapid recovery and appeared to be doing as well as might be expected in a subject of tubercular cystitis. She died within a few hours of the second operation, uremia supervening so rapidly as to leave little doubt of the cause of death, even though no autopsy was performed.

The year 1894 witnessed two attempts by Duplay and one by Rein to transplant the ureters to the bowel; all three ended fatally. Trendelenburg in 1895 removed one kidney and the bladder for tuberculosis of the urinary tract, transplanting the remaining ureter into the sigmoid. The patient so soon died of tuberculosis of other parts of the body that the outcome of the ureteral transplantation was left in doubt.

The year 1896 witnessed the most important contribution to the technic of ureteral transplantation made up to that time. This was the procedure designed and carried out by Karl Maydl, acting upon the conception that retaining the ureteral orifices intact would preserve their natural powers of preventing regurgitation, and thus do away with the ascending infection which had hitherto rendered successful transplantation into the rectum practically impossible. He therefore resected the entire trigone (exposed in the classical cases of ectopia vesicae) made an incision in the adjacent sigmoid, carried the section of bladder bearing the two ureteral orifices through this, and affixed it in place with sutures. This operation was first carried out June 19, 1892, but was not reported until some years later. The original patient was living in good health in 1899. Of 9 patients subsequently operated upon, 1 died of shock the next day. This was the only fatality. The remainder were all alive in 1899 and evincing no symptoms of renal disturbance.

Maydl's method rapidly attained popularity in Europe and was performed with no important modifications until 1905 when the English surgeon Moynihan used it with so radical a departure from the original plan that it was later known as the Maydl-Moynihan technic. Though the British surgeon's patient was a sufferer from exstrophy of the bladder, the case differed slightly in that extensive attempts to close the bladder wall had been made during the patient's childhood, and extensive cicatricial formations hin-

dered the work of transplanting the ureters. The bladder was dissected up and as much tissue as possible left about the ureteral orifices; the ureters were outlined by catheters and when the section of tissue about their openings had been dissected entirely free it was drawn up toward the umbilicus, exposing the rectum in the bottom of the wound. The peritoneum was carefully stripped up and a rent accidentally made in it hastily repaired. A $3\frac{1}{2}$ inch incision made in the rectal wall was held open and:

Into this opening the bladder was placed, being turned upside down so that its former anterior surface became posterior, and its former lower end became the upper. The ureters instead of passing forward to the bladder pass backward, and the catheters passed into the rectum and out at the anus. The edge of the bladder and the cut edges of the rectum were now sutured together, by two stitches that were continuous, one taking the right side and the other the left.

Lembert sutures were used without including the mucous membrane. The catheters were left in for four days. Thereafter, the urine dribbled from the rectum, as the anal sphincter had been stretched to facilitate the operation. Control of the sphincter was gradually reestablished, and was perfect at the expiration of a month.

The ultimate result of Moynihan's modification is to make a cloaca resembling somewhat that found in early fetal life or in birds. The transplanted bladder forms a pouch which assists in holding back the urine and making it possible for the rectum to act as a reservoir for liquid as well as solid excretions.

Commenting upon Maydl's original procedure, Peterson describes it as a "uretero-trigono-intestinal anastomosis." In his thesis published six years after Maydl's first presentation of his work, Peterson includes a table of 36 cases operated on by this method, and remarks:

The mortality in the 36 operations is surprisingly low when it is considered that

it is a difficult major operation and that the list includes the first cases operated upon before the technique had been perfected. When we compare this mortality with the 33 per cent mortality accompanying ureteral implantation without the preservation of the ureteral orifices, we are forced to conclude that the explanation lies in the intrinsic dangers of the latter operation rather than to a lack of skill on the part of the operators. Without the vesical ureteral orifices 11 deaths in 33 cases from rapidly progressive renal infection; with the ureteral orifices intact, 5 deaths out of 36 cases; 2 at least not being due to infection . . . The 6 fistulae resulted, in some of the cases at least, from timidity on the part of the operator to trust to his suturings and to the employment of gauze drainage. They are all reported as eventually closing. The noting in 5 cases of gradually disappearing lumbar pains would suggest a possible renal infection from which the patient slowly recovered . . .

"The number of cases (10) living without signs of renal infection" after two years, is encouraging.

The method employed by Boari in the same year (1894) differed considerably from those previously used. But as the 2 cases (his own and that of Casati using his method) were both unilateral, no final judgment as to the value of his innovation could be made. By means of an anastomotic button the Italian surgeon united the left ureter with the descending colon, doing the operation extraperitoneally through a curved incision. The posterior parietal peritoneum was opened to secure the colon, but closure was made extraperitoneally. The patient was alive and well six months after operation, but no information as to the state of her kidney could be recorded. Casati's patient had advanced vesical tuberculosis. Implantation of the left ureter into the colon by the button method was done, with the intention of doing the right side later and removing the bladder entirely. The tubercular infection proved fatal in five weeks so the second step was never done. No autopsy was secured.

Another mechanical contrivance was a

hollow nickel tube with cone-shaped ends devised and used by Chalot in 1896. The rectal end was slightly larger than

to their lower portions. A large drainage tube was left in the rectum for a considerable period. The urine passed by this

that designed to hold the ureter and provided with a hole through which a thread might be tied to assist in withdrawing the tube later, should this prove necessary. The smaller end was grooved so that it might hold a loop of thread thrown about it to hold the ureter in place after it had been slipped over the end of the tube. Chalot used this device in a case of uterine cancer involving the broad ligaments. He first isolated the left ureter, cut it off high up and joined it, by means of the button, to the rectum. He then ligated the internal iliac artery. The same manoeuvre was carried out on the right side, including ligation of the artery. Little hemorrhage accompanied the subsequent removal of uterus and adnexa. The bladder was not involved apparently, the reason for transplanting the ureters being that removal of the malignant area was impossible without irreparable injury

channel from the outset and no rise of temperature gave evidence of infection having taken place. For the first month the bowel evacuations occurred once or twice an hour and were diarrheal in character. Convalescence was otherwise uneventful. The report was made two months after the operation was performed. The patient was in excellent health, all wounds healed and urine passed per rectum only three or four times daily. No record can be found of the eventual fate of this patient.

In the United States a new plan was devised by George R. Fowler, who exposed the ureters by incising the posterior layer of peritoneum through a median abdominal incision. (See Fig. 1.) The ureters were then severed at their bladder extremities. The anterior wall of the rectum was incised through the serous and muscular coats, which were then retracted, leaving

a diamond-shaped area of mucous membrane. A tongue-shaped flap, having its base upward, was then cut in this space, doubled back and sutured to form a valve covered on both sides with mucous membrane. In the opening thus made through the entire wall of the rectum, the cut ends of the ureters were now drawn and sutured so that their obliquely severed ends lay upon the mucous membrane of the flap. The flap was then pushed into the rectum and the wall closed by catgut sutures. Fowler did this operation upon a boy of six years who had exstrophy of the bladder. In Peterson's monograph is quoted a statement from Fowler, made three and a half years afterward (the exact date of Fowler's intervention was September 20, 1896) to the effect that the boy was then in perfect health and had never given any indications of being affected with any urinary tract disturbance traceable to infection. Other operators who endeavored to imitate Fowler were not so fortunate. Three years later W. C. Wood reported the death of a patient from pyelonephritis, two months after he had been operated on by the Fowler method.

Several European cases were reported during the next three years, but all the successful ones prove on examination to have been unilateral (Tuffier and Schnitzler). In the attempts to do bilateral ureteral transplantations made by Tuffier and Du Jarnier (1896), Fritsch (1897), von Winiwarter (1898), and Schnitzler (1898) fatal renal infection occurred subsequently in each instance. Turetta's employment of Boari's button in a bilateral ureterorectal anastomosis in 1899 also terminated in a suppurative nephritis.

The publication of Peterson's thesis during the last year of the nineteenth century showed transplantation of the ureters to be a highly hazardous undertaking, only serviceable in the treatment of exstrophy of the bladder, and to be used for this solely in cases where the patient's condition was regarded as so desperate that death itself would be

preferable to continuance of life under the congenital condition. The few patients who had survived the operation for a long enough time to warrant the drawing of conclusions had undergone the procedure designed by Maydl: anastomosis of the trigone with the sigmoid or rectum, or that initiated by Bergenhem and variously attributed to Peters or Pozza: transplantation of each ureter separately, with a surrounding rosette of bladder wall, into the rectum.

A very careful consideration of the entire course of animal experimentation, beginning with that of Glück and Zeller in 1881, is included in Peterson's paper. The procedures followed by the different experimenters he divides into eight groups:

1. The severed ureter is inserted into the intestine through a small incision in the bowel wall and secured to the latter by sutures, which are passed through the intestinal serosa, and then either through the peritoneum removed with the ureter or its fibrous coats. (Glück and Zeller, Tuffier, Reed and Martin.)

2. A small incision is made through all the coats of the bowel and the ureteral and rectal mucosa sutured. The incision is then carefully closed about the ureter by Lembert sutures. (Morestin.)

3. A v-shaped flap is formed in the anterior intestinal wall, to which the ureters are sutured. This flap is buried by suturing over it the lateral folds of the bowel wall. (Vignoni.)

4. A rectangular flap containing the ureteral orifices is inserted into the bowel through an incision in its anterior wall. This flap is sutured to the freshened mucosa on the posterior wall of the bowel. (Pisani.)

5. A ligature with a needle at each end is passed through the end of the severed ureter. The needles are passed through a small slit made in the bowel wall and brought outside the intestine from $\frac{1}{2}$ to 1 inch below. The two ends are made taut and the ureter is drawn into the bowel. The ureter is then secured in position by sutures. (Bardenhauser, Reed and Van Hook.)

6. The ureters are buried under the serosa and muscles of the intestinal wall and secured in place by sutures uniting

the ureter itself was subjected to a mini-

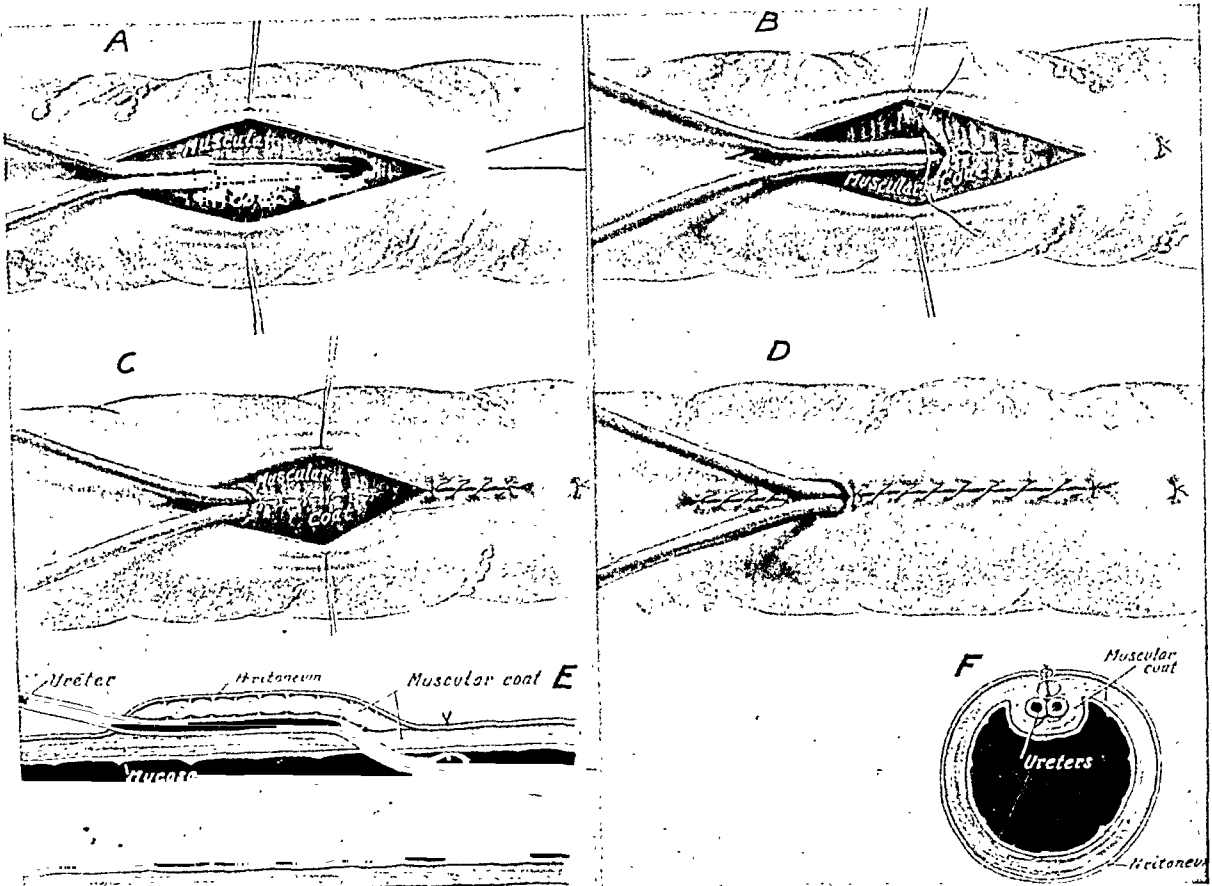

FIG. 2. Martin operation. (After Coffey.)

the ureteral and intestinal mucosa, or drawn into the bowel, as described under Method 5. The muscular and serosal flap is then sutured over the ureters. (Krynski and Martin.)

7. The ureters are secured to a mucosal flap valve and buried obliquely under the serosa and muscularis. (Duval and Tesson.)

8. The anastomosis of the ureter and intestine is made with a mechanical device, which, after union is secured, passes into the intestine. (Boari.)

In all types of work the primary mor-

num of suturing gave the best results. The most important experimental work done in this country had been that of Martin, the results of which were published in 1899. As a gynecologist, Martin's interest lay in disposal of the ureters in cases where extensive surgical removal of the female pelvic organs had been undertaken, whereas practically all the work done by others had the treatment of exstrophy of the bladder as its aim. Martin states the idea underlying his experiments as follows:

1. The ureters should empty into the bowel in the direction of its long diameter from above downward, so that the urine shall be discharged in the direction of the fecal current. (See Fig. 2).

2. The ureters are buried in the walls of the rectum for a distance of an inch or more, longitudinally, so that in the act of defecation, the fecal mass will close the caliber of the ureters by its pressure on the mucous membrane, and that pressure is exerted from above downward in the direction of the onward flow of the urine, thereby emptying the ureter by a milking process. (See Fig. 2.)

3. The ureters are further protected by the muscular coat of the intestine. This is accomplished by surrounding them in their longitudinal course through the intestine to the extent of 2 cm. by the muscular coat of the bowel. This muscular coat of the bowel in acting from above downward milks the urine downward and holds the ureter closed when the rectum is aiding in defecation. When the contraction and closure due to defecation is over, the urine will spurt forth with considerable force, acting as a cleanser to the ureters.

Martin operated 4 human cases. In 3, death followed almost immediately, but as the condition of the patients was desperate before the intervention was undertaken the fatal outcome could not be justly attributed to the ureteral transplantation. In a case of exstrophy of the bladder only one side was done. Martin's experimental work appears to have been the most extensive, as well as the most thorough, of any of which I have found records up to the year 1910. The fact that he finally abandoned the attempt to find a clinically satisfactory method of transplanting the ureters is the most unfavorable comment possible upon the possibilities and probabilities which the subject held out. When he gave up animal experimentation, he stated that he was convinced that work along these lines would never be crowned with success.

The care of an animal cannot be such that one can minimize, as in the human, several sources of danger of infection. Gravity, as it is exerted on the urine in the ureters in the upright human, is lacking in the horizontal animal. The rectum of the human patient can be rendered and maintained relatively clean. The usual location of the implantation in the animal . . . makes the mouths of the ureters the most dependent portion of the bowel . . . much more subject to infection. The human . . . patient can be so controlled that ureteral catheters can drain the ureter for several days after operation and the mouths of the ureters [be] protected entirely from infected material, thus giving a start and an immunity when the resistance of the tissues [is at its lowest].

It is to be regretted that no human case ever came into Martin's hands wherein he might have had a fair opportunity to demonstrate the truth of these assumptions.

BERGENHEM'S PROCEDURE

Although Peterson lists in his bibliography the operated case reported by Bergenhem of Nyköpings, Sweden, in 1894, no other mention of this procedure is made in his monograph. This came out November 30, some months later than the two publications made by Maydl in the same year. It is emphasized by Buchanan that Bergenhem's procedure was *the first extraperitoneal implantation of the intact ureters, with rosette of bladder attached, by separate openings into the rectum*. The patient upon whom the operation was carried out presented an adenoma having its origin in an ectopic bladder. This growth was first removed. A month later all the bladder wall was excised with the exception of two small oval sections which were allowed to remain about each ureteral orifice. It was the operator's intent to work entirely outside the peritoneum. Unfortunately it was twice accidentally opened, but these wounds were immediately sutured. After the ureters had been freed by blunt dissection, the rectum was exposed by a transverse incision in the perineum. Two small anterolateral incisions were made in the

rectum, and through these the sections of bladder wall, carrying with them the ureteral orifices, were drawn and fixed

himself carried out a practically identical procedure. He failed to make any explanation as to why he waited so many years

in position, using but one stitch for each ureter. (See Figs. 3-7.)

It was reported by Jaja of Florence, Italy, in 1901, that seven years prior to

making this report, that is, on May 13, 1894, six months before Berghem published his case, the Italian surgeon had

it casts some doubt upon its exact nature. The honor of originating the idea of transplanting the ureteral orifices intact

into the bowel must, therefore, be accorded to Bergenhem. Following the Swedish author's publication the operation was

the first transplantation effected by an extraperitoneal route." His case was a very remarkable one in many respects,

FIG. 7. Bisected bladder and intersymphysial band. Transplanted ureters in place with bulging peritoneal overlying sac. (After Hutchins and Hutchins.)

FIG. 8. Peter's operation. Scheme of transplantation of ureters into rectum by extraperitoneal method. Ureter (a) in transplanted position with (b) rosette of bladder mucous membrane and muscle; (c) catheter stitches into ureter by suture at (b) and protruding through (e) anus; (d) forceps passed by anus through opening in bowel and grasping catheter; (f) reflection of peritoneum. (After Coffey.)

done by Pozza (Italy) in March 1897; by Franklin H. Martin (United States) in 1898, as a two-stage procedure; by Capello (Italy) in the same year; by London (Australia) May 12, 1899, and by George A. Peters (Canada) on the fifth of the following July. Probably because the periodical, *Eira*, in which the operation was originally described, was practically unknown to English-speaking medical men, Peter's name has remained attached to it in this country and England, while in Italy it is called Pozza's operation. It is evident, nevertheless, that Bergenhem was its originator, his work having preceded Pozza's by two and a half years, and that of Peters by almost five years.

Peters apparently knew nothing of the work previously done by Bergenhem. In the account which he published in the *British Medical Journal*, June 22, 1901 he says: "The operation . . . is, I believe,

as the patient suffered not only from congenital exstrophy of the bladder but had developed a severe procidentia recti, due to absence of the pubic arch. The rectal condition was first successfully remedied, and not quite three years later Peters undertook to establish urinary continence by transplanting the ureters into the bowel. The technic employed was practically the same as Bergenhem's, but Peter's criteria of selection for the site of implantation upon the intestinal wall are worthy of notice. The requisite qualifications are:

- (1) It must be above the internal sphincter;
- (2) It must be in the lateral and not in the anterior wall, so as to avoid kinking. (See Fig. 8.) (This actually occurred in the first

instance in Peters' case, necessitating a subsequent adjustment of the implantation.) (3) It must be high enough to permit the ureter to project slightly ($\frac{1}{4}$ to $\frac{1}{2}$ inch) into the lumen of the bowel without stretching. If the ureter thus projects it will form a papilla, which, when pressed up from within the bowel, becomes converted into a valve, similar to that at the entrance to the bile duct and the salivary ducts.

He made no attempt to stitch the ureters in place, deeming the precaution unnecessary. The catheters were left in place until they "came away of themselves," which happened in about sixty hours.

A year and a half after operation the boy was in perfect health. "There has never been the slightest tendency to a return of the prolapse . . . no evidence whatever of a disturbance in the function of the kidneys. On examination *per rectum* the mouth of each ureter can be felt as a salient papilla as large as the tip of one's little finger." The child frequently held the urine all night, and the daytime intervals of urinary evacuation were normal for his age and condition.

This report attracted wide attention both in North America and Europe. In the ensuing decade a respectable total of cases were reported as having been performed by "Peters' method."

THE FIRST DECADE OF THE TWENTIETH CENTURY

The technic of Maydl being much more widely known than that of Bergenhem, practically all the attempts made to transplant the ureters during the first ten years of the twentieth century were performed in accordance with this method. As early as 1903 Orlow, a Russian writing in French, was able to collect and tabulate 61 cases of exstrophy of the bladder which had been operated upon by Maydl's method of ureteral transplantation. In 7 of these cases the operators had varied considerably from the technic originally outlined by Maydl. The others followed his directions exactly, or with unimportant

modifications. Among those where the technic was considerably varied are to be found the procedures of Bergenhem, Capello and Pozza, showing that Orlow regarded Bergenhem's method as being merely a modification of Maydl's.

Omitting these 3 cases, Orlow's researches show that 13 patients died almost at once, 2 succumbing to a previously existing pyelonephritis. The immediate mortality was, therefore, 17 per cent. Five deaths were due to peritonitis; 2 to pneumonia, 1 of them being complicated by a metastatic parotitis; 2 to the effects of prolonged narcosis, and in 2 the direct reason for the rapid fatality was not given. It may be remarked that none of these deaths was caused by the ureteral transplantation *per se*; similar fatalities may follow any prolonged and difficult major operation. However, in one of Orlow's own cases he attributed the fatal outcome to his having put in but one layer of sutures; in Eiselberg's case, the sutures pulled away because of too great tension upon the trigonal implant; Bucheri included a ureter in his suture—all faults of technic.

Summing up the functional results in the cases surviving, it was found that on the average the patients were able to make the sphincter and retain the urine during the day, so that micturition was practically normal, and many of them were continent during the night also, although most of them were obliged to rise at least once. The operation thus should be adjudged successful in abolishing urinary incontinence. Estimate of the more remote results is rendered rather difficult by the fact that many of the patients were not followed for more than a short period, if at all. Yet some were under observation for three years or more. Six cases of pyelonephritis causing death eventually were found among the 45 patients surviving the operation, that is $12\frac{1}{2}$ per cent. But these cannot positively be charged to the effects of ureteral transplantation, inasmuch as it is well

known that ectopia vesicae unoperated is prone to develop kidney infection.

EARLY VARIATIONS OF MAYDL'S TECHNIC

Graubner introduced sounds into the ureters and dissected them out with a portion of the bladder wall surrounding their orifices. A transverse incision, 4 cm. in length, was made in the sigmoid, and the ureters separately sutured into this incision with two layers of stitches. Mukulicz made use of the rectum instead of the sigmoid as a site for the transplantation of a section of bladder wall bearing both ureters. The results were poor; the patient was obliged to wear a urinal, and died within four months of pyelonephritis. Malinowsky first laid his patient face downward and exposed the rectum by the lumbar route; he was then turned over and all of the exstrophied bladder cut away, leaving the ureters attached to it. The peritoneum was not opened. The patient was thereafter turned once more upon his face, an incision made in the exposed rectum, the cellular tissue stripped from its surface, the freed bladder drawn toward the anterior wall the of intestine and sutured to the rectal incision. The patient died in six days. The object sought in so much altering of the patient's position upon the table was to avoid opening the peritoneum. Orlow, to whom I am indebted for the account of this Russian case, remarks that the procedure is "too complicated to permit many to become adept [in its performance]."

ANIMAL EXPERIMENTATION

In the first year of the century Jacob Frank of Chicago undertook some animal experiments upon direct implantation. Ten dogs were subjected to the following technic: The selected section of bowel was isolated; the peritoneal coat incised for a space of about $\frac{3}{4}$ inch, and the peritoneum loosened up and retracted; a $\frac{3}{4}$ inch incision was made in the remaining coats of the bowel. The cystic ends of the ureters were now severed and held

together by a silk suture. A needle armed with fine silk was passed from without inward, through all the coats of the intestine except the peritoneal, about $\frac{1}{4}$ inch below the lower angle of the incision, then emerging through the opening. The needle was passed through the cut ends of the ureters and out through the intestinal wall, the same distance from the incision that it entered. The ureters were then grasped in the loop of silk and the ends tied tightly together, drawing the ureters into position and holding them there permanently. The intestinal wound of muscularis and mucosa was sutured transversely, compression of the ureters being carefully avoided. The peritoneum was then closed. The sutures in the bowel being thus covered by peritoneum, infection is obviated.

In his comments Frank stated that "the technic is all that can be wished for," but he declared simultaneous bilateral transplantation to be impossible in human beings. His optimism is somewhat hard to comprehend in that all his dogs simultaneously transplanted, 4 in number, died immediately. Those whose ureters were transplanted one at a time survived longer, but all eventually succumbed. While his technic quite possibly "obviated" immediate surgical infection, it did nothing to solve the problem of preventing infection ascending from the bowel to the kidney.

Another method, demonstrated experimentally upon dogs, was that offered by W. Howard Barber of New York in 1915. All Barber's 8 dogs survived operation, 1 dying within a week from sloughing of the ureter due to overextension. He argued that the ureter is necessarily traumatized and reduced in its motor efficiency, and resistance is unavoidably piled up at its extreme caudad end. The problem, then, is so to reduce this terminal work as to render the already impaired ureter physiologically capable of meeting it. For this purpose he offered the following technic: A mesoventrad

incision 5 cm. long is made in the lower abdomen; the ureter is identified and freed from its bed, and divided between two ligatures, just cephalad to the bladder. A straight cutting needle is attached to the cephalad ligature and made to penetrate the sigmoid colon in a line perpendicular to its long axis. Driving the needle through at a point 90 degrees distant on the intestinal wall will draw the ureter through each wall. The sigmoid being suspended by the glass rod method, the ligated cephalad end of the ureter is allowed to protrude on to the skin where its ligature is affixed by a single suture. The wound is then closed about sigmoid and ureter. Six hours later the exposed ureter is incompletely cut and allowed to empty. It may be returned to the lumen of the intestine at any time thereafter, but it is well to retain it under control until its continued patency is assured. One or both ureters may be transplanted in this way within twenty minutes. I have failed to find any record of this experimental method having ever been clinically employed.

The year 1909 witnessed the revival of Bergenhem's technic by Buchanan of Pittsburg, and the first presentation by Coffey of the method which is now so well known under his name. Buchanan compared the mortality following Maydl's procedure with that which had attended to smaller series of cases operated upon by the method of separate implantation of the ureteral orifices. He concluded that the separate implantation of the ureters answer every purpose of trigonal implantation both with reference to the preservation of a blood supply and the guarding of the ureteral orifices against ascending infection. As of the 80 patients on record as operated by Maydl's method 23 had died (28.7 per cent), while of 26 to whom the Bergenhem technic was applied 3 only had died (11.5 per cent), Buchanan decided that the second method was to be preferred. The important point in any technic he considered to be the preven-

tion of ascending infection; the important factors in this prevention he listed as follows:

- (1) Each ureter should pass in a direct course, without kink or twist, to the point of entrance into the bowel;
- (2) there should be no injury by forceps, knife or needle, of or near the ostium, that could cause a cicatricial narrowing of the passage;
- (3) the intra-intestinal portion should keep its position without tension;
- (4) no injury should be done the ureter by retention sutures;
- (5) the ureteral catheter should be used as a guide in dissection through operation, but not as a conductor of urine afterward;
- (6) no dilatation of the sphincter ani should be practiced, a rubber tube to prevent distention being amply sufficient.

Finding that Bergenhem's procedure fulfilled these requirements better than any other within the range of his knowledge, Buchanan performed it first upon a ten-weeks-old-infant, and a year later upon a child of three years, both males afflicted with exstrophy of the bladder. At the exhibition of the second patient, the first was also shown, being in good health and able to hold his urine in the rectum for about four hours.

The method of ureteral transplantation devised by R. C. Coffey of Portland, Oregon, was first worked out in connection with implantation of the bile-duct into the intestine. Before the Section of Surgery of the American Medical Association in June, 1910 the first results of this experimenter's work were presented. The method (See Fig. 9) consisted of careful dissection of the ureter which was cut in two above a ligature, one end split and a linen suture passed through this split end so as to include about one-half of it. The suture was then tied and the loose ends threaded through two needles; the end of the duct was wrapped in gauze to await preparation of the intestine. An incision approximately an inch in length was then made through the peritoneal and submucous coats of the bowel of the selected spot, the mucous

membrane being allowed to "pout" through the incision. Five or six suture stitches pick up the peritoneal and sub-

the outside of the intestine. Tying of the intestinal sutures closes the opening in the peritoneum. To permit the ureter to slide easily into its new channel the mucous membrane must be loosened for perhaps $\frac{3}{4}$ inch. The ureter must therefore be tacked to the peritoneum at its point of entrance by two or three fine sutures of linen or silk, care being taken to penetrate only the outer coat of the ureter. "Thus practically all the steps of the operation are completed before the intestinal mucosa is penetrated and no sutures penetrate the lumen of the ureter."

SUMMARY OF COFFEY'S EXPERIMENTS

Of 9 dogs in which physiologic implantation of the ureter into the large intestine was done, 5 recovered and were in good health one hundred sixty-nine days, eighty-one days, seventy-five days and seventy-two days after operation, when they were killed with chloroform. One dog died on the thirteenth day without discoverable cause, the implantation being found perfect; 3 dogs died of peritonitis. In no one of the 9 cases did ascending infection take place. Six dogs upon whom direct ureteral implantation was done, the technic and surgical precautions being the same, all died immediately save one, which survived for sixty-one days, but was found to have lost practically all the secreting portion of the affected kidney, though the ureter had remained patent at its point of entrance into the intestine.

MAYO'S TECHNIC

In a recently published article, Coffey has stated that it was nearly two years after the completion of these experiments before he had a chance to make clinical trial of the procedure upon a human patient. During this period Charles H. Mayo, who had heard and favorably commented upon the original presentation, applied Coffey's plan to several patients sent to the Mayo Clinic for relief of ectopia of the bladder. (See Figs. 10-16.) The exact technic employed was described by Mayo

FIG. 9.

mucous coats at the edges of the incision, the suture at the upper end being tied as a control. The intermediate control sutures are lifted up on the flat handle of an instrument as they cross the incision, the intestine brought down close to the end of the split duct, the two needles carrying the traction sutures are passed beneath those holding the edges of the cut intestine, through a stab wound in the mucous membrane into the lumen of the intestine and then out again through the intestinal wall, $\frac{3}{4}$ inch farther along the intestine. The points of the needles should emerge about $\frac{1}{8}$ to $\frac{1}{4}$ inch apart. Traction exerted on these two threads now draws the ureter into the lumen of the intestine where it is fixed by tying the threads of

in his contribution to the Osler Anniversary "Contributions to Medical and Biological Research," published in 1929, as follows: A lateral abdominal 4-inch incision is made, locating the ureter behind the peritoneum, in the pelvis. The peritoneum is then incised midway in the pelvis, this further exposure permitting 2 inches of the ureter to be dissected free. An inch from the bladder wall the ureter is divided between forceps, its lower end ligated, and closure of the peritoneum effected by running suture to the point of emergence of the ureter's proximal end. Judd, Mayo's colleague, modified this procedure slightly by making a lateral abdominal incision to the peritoneum, exposing and dividing the ureter extraperitoneally, opening the peritoneum at the point of its ureteral attachment, drawing out a fold of sigmoid to which the ureter was anastomosed outside the peritoneum, and finally replacing the bowel within the peritoneum over the incision to which it is sutured.

Right side anastomosis is made as low as possible. Opposite the isolated ureter a $1\frac{1}{4}$ inch incision is made through the bowel's outer coats in the line of the longitudinal muscles, carried to, but not through, the mucous membrane. The tissues lateral to the incision are slightly separated, and a puncture made at the lower end large enough to receive the ureter, the lower end of which is split for $\frac{1}{4}$ inch. A curved needle carrying No. 0 catgut is then passed through the tip of the ureter and tied, the short end of the thread being cut away. Passed through the opening into the intestine and emerging $\frac{1}{2}$ inch below its point of entrance, the needle carries the thread, which when drawn upon, brings the ureter's end within the lumen of the intestine. Passing the needle through a fold of intestine at its point of emergence ties and fixes the ureter in its new location. It is further fixed by interrupted sutures used to approximate the divided peritoneum and muscle of the intestine, every other one of which catches a bit of its outer wall. At the upper

angle of the incision an adjacent fat tag serves to relieve ureteral pressure, being held in place by a stitch. Another row of

continuous stitches over those first set in gives additional protection. And still other stitches adjust the bowel to the parietal peritoneum in such a way as to avoid kinking of the ureter and prevent traction upon it.

By this procedure the ureter is incorporated into the bowel wall in such a way as to be covered only by the mucous membrane for a distance of $1\frac{1}{4}$ inch before it actually enters the lumen of the bowel. Thus any internal pressure will promptly close off the ureter. There has been estab-

lished a duct entrance similar to any other duct entrance elsewhere in the body, which is shut off by the pressure of

subsequent right-sided procedure exceedingly difficult, it has been found wise to make the first intervention upon the right.

it can be retained in most patients for the normal period between micturitions, two, four, or in adults, as long as eight hours.

At the end of the period covered in the article in the Osler Anniversary volume,

rarity of the anomaly. Six were treated by plastic repair; 3 operated upon by the Maydl-Moynihan method (2 dying of uremia); and 26 had had ureteral transplantation by the method just outlined. Four of these patients died shortly after

operation. Of the remaining 22 successful cases, there were 2 in which there was a solitary kidney.

Up to the time the first report was given out from the Mayo Clinic there had apparently been little general interest evinced by the medical profession in Coffey's plan of ureteral transplantation. The Maydl operation as modified by Moynihan was most commonly employed, though there is a fair sprinkling of articles concerning the use of "Peters," that is Bergenhem's, procedure in the literature published between 1905 and 1920. The Moorheads, describing 2 cases of bladder exstrophy treated by a modified technic, gathered together records of 152 cases previously so handled, and in two publications on the same theme, make no mention of Coffey or the advantages which his technic offers over the older methods. William E. Lower of Cleveland, writing in 1923, says it is his own opinion that "some technic which insures the application of the principle proposed by Coffey should be adopted." This principle he quotes from Coffey himself as consisting of "submucous implantation of the duct for the purpose of reversing the course of static intra-intestinal pressure and bringing it to bear on the site of the duct . . . The essential mechanical principle necessary to uniformly successful implantation of the ureter is that the ureter shall be made to run immediately under the loose mucous membrane for a distance, before entering the lumen of the intestine."

Certain details essential to success in using the Coffey method are mentioned by Lower as follows: Preliminary to operation, the function of the kidneys, as for any intervention upon ureters or bladder, should be checked up by blood chemistry and the standard tests of renal efficiency. The bowels should be well cleared out two days before operation and a rectal douche given on the operating day. Guthrie's advice in regard to the Trendelenburg position should be followed, the patient being placed in this posture before being anesthetized. Suction

of the diaphragm will thereafter aid in pulling the intestines out of the pelvis. All abdominal viscera should be held out of the pelvis by efficient gauze packing. Lower later discarded Coffey's intestinal clamp, which he found unnecessary if the bowels had been thoroughly cleared beforehand. The dangers of urinary absorption are lessened by leaving a tube in the rectum until that organ becomes accustomed to its new content, and the free employment of saline rectal douches.

At the time of writing Lower had done 16 transplantations, 10 of them being done according to Coffey's technic: 3 for vesical carcinoma and 13 for exstrophy. The ages of the patients varied from four months to fifty-four years. Only one patient was lost.

HINMAN'S WORK

At about this same period Frank Hinman of California, with other workers at the University of that State, undertook a series of experiments in transplanting the ureters into the duodenum. The reason for selecting this portion of the intestinal tract as the site of implantation was the freedom from infection, one of the main drawbacks to all procedures upon the lower bowel. The supposedly greater absorption of urine, were it diverted into the small intestine, had hitherto kept investigators from employing this site for implantation. The results of the experiments do not assist us in any way in solving the problem of ureteral transplantation for cases where the bladder is missing or defective, or under any conditions which call for bilateral diversion of the urinary output. All the experimental animals died within twelve days of the time when the entire urinary output was diverted to the duodenum, either by bilateral transplantation of the ureters, or by unilateral transplantation and opposite nephrectomy. Except for a severe diarrhea in the terminal stages, the symptoms presented were identical with those following bilateral nephrectomy, with most marked nitrogenous retention in the blood.

The technic devised by Coffey seems now to have supplanted all others to a very great extent, at least so far as this continent is concerned. Abroad, reports of cases, more or less successful, wherein Maydl's method had been used, still continue to appear. Several Canadian physicians have recently given accounts of the present condition of patients operated upon by Peters, who died in 1911. All 5 are living, 4 in excellent health. One is known to be suffering from vesical infection but is still able to work at a trade. The so-called Peters' operation is still popular in Great Britain and its dominions.

During the past two years Coffey has published several considerable modifications to his technic, and a number of operators have given us accounts of their experience in using both his original and revised methods. McKenna, in a paper read before the American Urological Association in 1927, remarked that a review of the literature shows that the results of ureteral transplantation have been good in the hands of comparatively few surgeons, and it would be a wise plan for those who have obtained good or even fair results to favor us with details, not so much of the technic they employed, the details of which "are sufficiently well known," as of the functional, bacteriological and pathological results of the operation. He then proceeded to give an account of animal experimentation carried out under his own supervision. Four of the 5 dogs first subjected to operation died. "Death was not due to the Coffey technic but to our own fault in carrying it out." Perfecting the technic by removing all tension from the ureter after transplantation, and introducing the end far enough into the bowel, which they had previously failed to do, did away with ascending infection, and permitted the dogs to live to complete convalescence, thus providing material for functional and bacteriological study.

Coffey has expressed himself several times as disappointed that his operation had not found a wider field of application.

Up practically to the present time, no one has undertaken ureteral transplantation to the bowel for any condition other than exstrophy of the bladder. He continued his experiments in the hope of making the operation safe enough to permit its use as an alternative in carcinoma of the bladder, and similar conditions. In 1925 he developed what he now calls "the tube method," recently described in the following words: Mobilize and sever the ureter; insert a small rubber tube well up into the dilated ureter; place a strong linen thread around ureter and tube in order to anchor the tube, to close the ureter against intestinal infection, and to strangulate the ureter so that the tube may be automatically removed later on. After opening the intestine in the usual way, the small tube is passed through a stab wound in the intestinal mucosa and attached to a rectal tube which has been passed up by way of the anus. Traction on the rectal tube will draw the ureter into the intestinal wound prepared for its reception. This accomplishes submucous implantation of the ureter in exactly the same way as if no rubber tube were inserted in it. Coffey remarks:

By the use of the tube to transmit the urine through the edematous tissues surrounding the anastomosis, the kidney functions just as if the ureter was brought out through a loin wound or through an abdominal wound. Therefore, it appeared that both ureters might be implanted simultaneously with the same degree of safety that accompanied the implantation of one ureter, and there seemed to be no good reason why, in certain cases at least, the bladder could not be removed and the ureters implanted, making a complete operation at one sitting.

This technic was employed by George Gilbert Smith in 10 cases of inoperable cancer of the bladder. He reports that though the procedure suggested by Coffey was of value, so far at any rate as the use of the indwelling tube was concerned, but he deprecated the idea of bringing both ureters through the same incision in the bowel wall, "inasmuch as this

method causes the right ureter to be strung across the pelvis like a clothes line, and invites intestinal strangulation." Smith found that dealing with otherwise healthy children, as in most cases of bladder exstrophy, is a fundamentally different proposition from dealing with the majority of sufferers from carcinoma of the bladder, i.e. elderly people, constitutionally much depleted, who have little physical reserve or resistance and upon whom wounds cannot be expected to heal readily. To remove the bladder and implant the ureters in the rectum, "which has to be done at one sitting if done at all," is a very extensive procedure under the best conditions, and will prove too great an ordeal for most subjects of bladder carcinoma.

SUMMARY OF HISTORICAL DATA

Maydl. Up to the work of Maydl transplantation of the ureters into the bowel had been uniformly unsuccessful. Maydl's technic was the first making any attempt to provide against regurgitation of the bowel content up the ureter. Its chief lack was the failure to guard in any way against direct contact of the ureteral orifices with the fecal current. This greatly enhanced the dangers of infection. Yet the idea of preserving and transplanting the ureteral orifices with their normal anatomical valves intact was a distinct advance over anything which had been done in the past.

Bergenheim. The contribution of Berghem consisted in transplanting each ureter separately, each with its normal valve intact; and more important still, in performing the operation extraperitoneally, which considerably lessened the immediate operative risk. Peters' technic does not vary from Berghem's in any essential particular.

Fowler and Martin. The method employed by Fowler followed the principles of the Maydl procedure; that of Martin those which underlay the work of Berghem. Both of these operators introduced

a new element by realizing the necessity of providing valve formation when the ureters were to be directly transplanted into the sigmoid. Martin was the first operator to advance the idea of suturing the ureter within the rectal wall. Both Fowler and Martin failed to realize the necessity of preventing direct contact of the ureter with the infected bowel content.

Coffey. The technic elaborated by Coffey is but a slight modification of that put forward by Martin. Martin embedded the ureter in the rectum adjacent to the mucosa, and sutured the rectal musculature directly over it. Coffey proceeded upon the conception that the passage of the fecal current would exert pressure upon the ureteral opening in the bowel wall, thus closing it against the downward passage of feces. This would produce a valvular effect which would minimize ascending infection. Yet, in common with those who preceded him, Coffey exposes the cut edge (that is, the ureteral orifice) to direct contact with the bowel content. Reviewing these various procedures, it appears to me that the chief cause of failure has been the lack of protection from fecal contact afforded to the tissues of the ureter itself.

Therefore, the greatest obstacles to be surmounted in the transplantation of the ureters are: (1) Direct contact of the end of the transplanted ureter with the feces; (2) the lack of a canal or passage which would assist in avoiding this contact; (3) the non-existence of any valve or structure exerting valvular action. The requirements of a satisfactory technic are therefore: *removal of the ureteral orifice as far as possible from direct contact with fecal material, and closure by pressure of any possible avenue of infection.* To meet these requirements I have devised the following technic:

AUTHOR'S TECHNIC

The animals used were dogs subjected to several days' starvation before operation. Also 1½ oz. of castor oil twenty-four hours before operating. A soft soap enema

was given at 8 A.M. and one immediately before operation.

Incision is in the midline, extending

are held by means of sponges wet in saline solution. This exposes the rectum, bladder and ureters (Plate 1, No. 2). The bladder

PLATE I. Author's method.

1. Incision is made in midline, through skin and fat; recti muscles separated by handle of scalpel.
2. Gauze pushes intestines upward, holding them out of operative field; rectum exposed; ureters can be seen passing downward to bladder, which is visible in lower angle of wound.
3. Bladder is drawn downward and outward; ureters can be seen at their point of entry into bladder wall.
4. Left ureter divided and stump transfixed; right ureter caught between two clamps in act of being divided.

about 6 inches from the pubis (Plate 1, No. 1), through skin, musculature and peritoneum. (In the human subject only skin and musculature should be incised, respecting the peritoneum.) A self-retaining retractor is inserted and all bleeding vessels clamped and ligated. The intestines

is now grasped by an Allis clamp and drawn outward and downward from the pelvic cavity, exposing the point of entrance of the ureters into the bladder wall (Plate 1, No. 3). The ureters are clamped close to the bladder, and a second clamp placed slightly above the first. In

placing this second clamp great care must be exercised not to traumatize the ureteral tissues. The ureter is divided between the

tion being sedulously avoided, and particular attention being directed to the preservation of the small artery which

PLATE II. Author's method.

1. Ureters freed as high up as possible (for a distance of 8 or 9 cm.).
2. End of ureter held by two fine mosquito clamps; ureteral catheter about to be passed into open lumen of ureter.
3. Catheter passed into ureter for distance of about $\frac{3}{4}$ inch.
4. Two sutures passed through fibrous coat of ureter.
5. Sutures tied to hold catheter firmly in place.

clamps, and the vesical stump ligated and transected by suture (Plate I, No. 4).

The second step in the procedure is the freeing of both ureters for a distance of 8 or 9 cm., almost to the renal pelves. This dissection should be carried out with the utmost care, all unnecessary manipula-

accompanies each ureter (Plate II, No. 1). When freed, the clamp upon the end of the ureter is replaced by two mosquito clamps which are placed very carefully so as to grasp only the thin fibrous coat, holding the lumen of the duct free and unobstructed (Plate II, No. 2). A No. 6 or No. 7

ureteral catheter is now inserted for a distance of about 5 cm. This insures a gradual curve in the direction taken by the

the catheter, as the insertion of a catheter even the slightest degree larger than the lumen will induce pressure upon the blood

Wm P Didusch 1929

PLATE III. Author's method.

1. Hemostat being plunged through mesentery between two vessels, to make opening for reception of rubber-covered clamp about to be placed upon rectum.

2. Bladder returned to its position in abdominal cavity; stay-sutures have been placed on either side of rectum to act as landmarks for position of incision to be made for reception of ureters; rubber-covered clamp in position on rectum; purse-string suture set in below clamp, suture needle having been passed through serosal and muscular coats, but not mucosal lining of bowel.

3. Large-caliber needle attached to hyperdermoclysis outfit being plunged through area encircled by purse-string suture, for irrigation of rectum by mercurochrome solution.

4. Closure of opening left by withdrawal of needle by drawing up purse-string suture.

ureter, and prevents any kinking (Plate II, No. 3). The exact dimensions of the ureter must be considered in selection of

vessels with inevitable necrosis and failure of the operation. A catheter of proper size being in place, it is held in that position by

three No. 000 chromic catgut sutures (Plate II, No. 4). It is important that these sutures transfix the ureteral tissue as

means of a syringe, but re-testing at this point is necessary, inasmuch as the epithelial layer of the ureteral wall sometimes

Wm P Didusch 1929

PLATE IV. Author's method.

Technic of ureteral transplantation on right side; that on left side is carried out in same manner.

1. Making incision through serosa and muscularis down to mucosa of bowel wall. Incision is made lengthwise of rectum between two stay-sutures previously placed on right side.
2. Muscularis being separated from mucosa by means of scalpel handle.
3. and 4. Ureter, with inserted ureteral catheter, carried to upper angle of incision in rectal wall and fixed in position by stitches passed through fibrous coat of ureter but not through catheter.
5. Muscularis sutured over catheter to form tube; small opening made in rectal mucosa through which ureteral catheter will be passed.
6. and 7. Continuous suture run around entire circumference of mucosal orifice to insure permanent patency.
8. Ureteral catheter being passed through orifice in rectal mucosa into lumen of rectum.

close to the cut end as it is possible to place them (Plate II, No. 5). Suturing accomplished, the catheter is tested to make sure that it is patent. It should, of course, have been previously tested by

buckles so much as to occlude the orifice. All the preceding manoeuvres are carried out alike for both sides.

In the third step of the procedure, attention is directed to the sigmoid.

This is drawn up into the wound until its mesenteric attachment is exposed. An area in the mesentary is now selected

mately 14 to 15 cm. from the anus. The hemostat is plunged through the mesenteric attachment, preparing the way for

Wm. P. Didusch 1929

PLATE V. Author's Method.

1. Incision in rectal wall completely sutured, showing ureter entering at upper end.
2. Operation completed for both sides, ready for closure of abdominal incision. Rectum returned to normal position. Ureters can be seen entering rectum on either side.
3. Longitudinal section (semi-schematic) showing ureter with inserted ureteral catheter in position. After removal of catheter artificially constructed tube will act as valve when compressed by passage of fecal current.

where a hemostat can be passed between two vessels, the point chosen being approxi-

the applications of a rubber-covered clamp (Plate III, No. 1). This clamp shuts off the

rectum from the upper portion of the bowel but is sufficiently high up (14 to 15 cm. above the anus) to afford abundant room for the transplantation of the ureters. After placing the clamp, a purse-string suture is set in upon the outward curve of the bowel wall, the needle being passed through but two of its coats, that is, *down to, but not through* the mucosa (Plate III, No. 2). A large-caliber needle connected with a one-quart hyperdermoclysis outfit, is now thrust through the space encircled by the purse-string suture. Through this needle 500 c.c. of 1 per cent mercurochrome solution is allowed to flow into the rectum, thoroughly cleansing and disinfecting it. (Plate III, No. 3.) During the passage of the solution, while it is inflating the rectum, gentle massage upon the rectal wall is performed. This assists in saturating the rectal mucosa with the solution, which then passes out through a rectal tube previously left in position. The irrigation completed, the needle is withdrawn, and the puncture-hole immediately obliterated by drawing up of the purse-string suture (Plate III, No. 4).

Two stay-sutures (shown in Plate III, No. 2) are set in either side of the rectal wall, serving not only to hold the rectum upward, but also as landmarks to indicate approximately the position of the incisions about to be made in the rectal wall. The incision is made between the two stay-sutures, lengthwise, through serosa and muscularis, but leaving the mucosa intact. In making the incision great care must be exercised not to injure the vessels or in any other way to impair the blood supply (Plate IV, No. 1). The edge of the incision is now picked up and serosa and muscularis carefully separated by blunt dissection from the underlying mucosa, the separation being carried for a distance of about 1 cm. on each side (Plate IV, No. 2).

The ureter with catheter inserted is brought to the upper angle of the incision in the bowel wall, where it is placed in direct contact with the mucosa. A suture of No. 000 chromic catgut is passed through serosa and muscularis of rectal wall and

through the thin fibrous coat of the ureter, transfixing the ureter in position (Plate IV, Nos. 3 and 4). Serosa and muscularis are then brought together over ureter and inserted catheter, interrupted catgut sutures being used. The catheter, extending beyond the cut end of the ureter, holds open an artificial tube or canal, continuing to within 2 cm. of the lower angle of the wound. When closure of this tube or has been completed to this distance, the edges of that portion of the wound still remaining open are held apart by two mosquito clamps, which grasp mucosa and muscularis, exposing mucosa. Note that up to this point in the operation the rectum has remained unopened. This greatly minimizes the chances of infection taking place. The surrounding organs exposed in the wound are now packed off with aseptic gauze and the exposed rectal wall painted with 2 per cent mercurochrome. By plunging a sharp bistoury through the musoca, an opening not more than 0.5 cm. in diameter is made at the lower angle of the rectal incision (Plate IV, No. 5). To insure the permanent patency of this opening, it is "button-holed" by a continuous silk suture, encircling its entire circumference (Plate IV, Nos. 6 and 7). When suture of the "golf hole" has been completed the catheter is inserted through it into the lumen of the rectum and passed out through the anus (Plate IV, No. 8). The lower angle of the incision in the bowel is now sutured, completing its closure (Plate V, No. 1). The procedure in regard to both ureters is identical. The completed operation, showing the position of both ureters, is depicted in Plate V, No. 2.

The mechanical advantages obtained by the procedure just outlined are schematically represented in Plate V, No. 3. The ureter is shown entering the wall of the rectum between the serosa and muscularis above and the untraumatized mucosa below. The catheter is shown emerging from the cut end of the ureter and proceeding for a distance of about 5 cm. between the two upper and the

under coats of the rectal wall, before it passes through the permanent "golf-hole" in the musoca into the lumen of the rectum. There is thus provided an artificial tube or canal some 5 cm. in length, which intervenes between the extremity of the ureter and the fecal canal. This artificial tube, after healing of the sutured incision and removal of the catheter, will present only its wall of thin rectal mucosa to the fecal current, so that it will be readily

compressed by the passage of this material, thus affording a valvular action. The desiderata mentioned in a preceding paragraph have thus been obtained. Direct contact of the ureteral orifice with the fecal current is eliminated, and a collapsible tube with valvular action provided, minimizing the chances of infection. I wish to thank Dr. Clyde Deming and Dr. Vincent Vermoaten for their wholehearted cooperation and assistance.

THE CAUSATION, PREVENTION & TREATMENT OF POSTOPERATIVE DISTENTION OF THE ABDOMEN*

EDGAR A. VANDER VEER, M.D.

ALBANY, N. Y.

THERE probably is no more serious complication that confronts the abdominal surgeon than that of an acute intestinal obstruction, no matter what its cause, following some abdominal operation. Though this condition is called by various names, such as acute dilation of the stomach, ileus paralyticus, dynamic ileus, pseudo-ileus, the situation is always the same, namely, an enormous distention of the stomach or intestines without seeming power on their part to overcome it. The record made by the American Association of Obstetricians, Gynecologists and Abdominal Surgeons in assisting in clearing the way for a better understanding of surgical abdominal lesions is one in which we may feel a sense of good work accomplished at a time when progress everywhere in our profession has been so great, and yet to the active abdominal specialist there comes the full realization that in some channels we have much to understand to make more positive our saving of life.

What can we do to help the earnest research workers to unravel the hidden truths that bear upon the suddenly dilated stomach, the intestinal obstruction of the upper half of the intestinal tract and death after a most satisfactory operation? What is more distressing, when making the first morning visit, to have the house surgeon approach somewhat hurriedly with the statement, "Mrs. W., whom you left in such a fine condition last evening, has within the past hour given me much anxiety. I do not like her symptoms, and may we visit her at once?" We see the patient and recognize immediately a case of an acutely dilated stomach or upper intestinal tract. As we study her appear-

ance and the chart and recorded history we realize the desperate condition this patient is now approaching, and it exhausts our physical makeup and mental power more than the half dozen major operations performed the preceding day, And why? Because our line of treatment and that of many excellent operators has brought such a sad mortality. Sir Astley Cooper as early as 1823 in the *London Lancet* wrote upon the subject of acute intestinal obstruction, and ever since that time acute dilation of the abdomen has been in the fore in our surgical meetings.

CAUSATION

An acute intestinal obstruction may be due to one of three causes: It may be purely mechanical in character, due to a band of adhesions, a kinking of the bowel, or some other cause where the obstruction is purely mechanical in character and not due primarily to some pathological condition in the bowel or abdominal cavity. The treatment here, of course, is immediate operation as soon as the condition is recognized. With this type of obstruction this paper does not concern itself. The second type of acute intestinal obstruction is that following a local or general peritonitis occurring either before or after the abdominal operation, and the third type of acute intestinal obstruction is that for which in lieu of a better term we use the name paralytic ileus or intestinal paresis.

Postoperative distention is most frequently due to paralysis or obstruction. In either event there is a failure of intestinal contents to move forward. If the obstruction is mechanical we have the protective mechanism of reverse peristalsis and vomiting. If it is paralytic this

* Read at the 41st annual meeting of the American Association of Obstetricians, Gynecologists and Abdominal Surgeons, Toronto, Sept. 10-12, 1928.

protective mechanism does not come into play; for the same forces that prevent onward peristalsis also prevent reverse peristalsis. In either event we have the absorption of intestinal contents with their concomitant effect on the metabolism of the individual.

When, at the time of operation, peritonitis has obviously begun, we can be fairly sure of an acute distention of the intestine later on. But this is a condition that the abdominal surgeon is not responsible for unless he has been careless in his technique, and while it does cause anxiety, it should not cause as much as when it appears unexpectedly and upon one of our most important cases.

Another cause of postoperative distention is unnecessary exposure of the abdominal viscera. Rough handling of the viscera plays an important part in postoperative abdominal distention. The abdominal viscera are delicate organs, and it is therefore reasonable to assume that they will resent any undue familiarity with them in the way of rough handling.

Furthermore, after a prolonged operation where much repair work has been done, the probabilities of acute dilatation are much greater, though we handle the intestines and other abdominal organs as gently as possible. Naturally the nerves of the intestines resent this prolonged handling and take this method to show their resentment.

Excessive hemorrhage, causing an anemic condition of the intestines, is a causative factor that must not be overlooked.

Another type is unquestionably due to an absorption of a certain amount of toxins from an overloaded intestine which has not been properly cleaned before operation.

Again there is a type to which we can give no reasonable explanation, and in which, even after an autopsy, we can find no cause, and which we must ascribe to some nervous peculiarity on the part of the patient.

Whether the type of anesthesia used (chloroform, straight ether, ether and oxygen, nitrous oxide and oxygen) enters into the causation has never been susceptible of demonstration. Other causes advanced for this condition are:

1. Drainage of the abdominal cavity, packing abdominal cavity with gauze during operation.

2. Too much surgery performed at one operation.

3. A too superficial examination of the patient before operation to determine whether any nervous defects are present.

Any or all of these factors may enter into the causation of the condition which we are discussing.

PREVENTION

As regards the prevention of this condition, I believe first of all that the majority of us are inclined to do too much surgery in the abdominal cavity at one operation. Because mechanically it is so comparatively easy to do a hysterectomy, cholecystectomy and appendectomy at one operation, is no reason that we should do so even on the most robust of our patients. I would prefer to perform two or three operations on one patient at different times, than to perform them at one sitting and have him subsequently run the risk of developing a paralytic ileus with its attending dangers and worries. In other words, the less surgery we do in the abdominal cavity at one time, the better. Also a thorough examination of the patient before operation is very essential and as little and as gentle handling of the abdominal organs as is possible.

TREATMENT

The treatment of postoperative distention is most disappointing, and but seldom successful, especially in the cases of postoperative ileus, and it is that particular class of cases to which I wish to call attention, together with the line of treatment followed in our clinic. In the treatment of these cases we are con-

fronted with factors not often considered. I refer to certain metabolic changes that occur in intestinal stasis. For the past four years I have been following every such case with detailed metabolic studies and am convinced that the following sequence of events occurs. First there is a decrease in the plasma chlorides followed by an increase in the non-protein nitrogen of the blood, both of which are associated with an increase in the carbon dioxide combining power of the blood plasma. A rising non-protein nitrogen is a serious omen and when it reaches 100 mg. or more the patient seldom recovers. I have found this simple observation of great prognostic value and estimating the non-protein nitrogen is one of the first things I always do in all cases of intestinal stasis.

Without going into detail it is sufficient to say that we have abundant experimental and clinical evidence that these metabolic changes are primarily of intestinal origin and that they can and do exist with little if any kidney impairment.

Reduced to terms of practical post-operative management the appreciation of this changed metabolism becomes of supreme importance. It is not enough that we direct our efforts toward relieving the stasis. We must also treat this altered metabolism.

In the face of a definite paralysis I do not believe surgical pituitrin is of much help. Occasional cases may be benefitted but as a routine it fails. These patients should have rest and to this end I avoid cathartics. Hot packs are applied over the entire abdomen and changed hourly except when the patient is sleeping; in such an event he is never disturbed.

The rectal tube and repeated enemas are useful in relieving the lower bowel but for distention high up they are useless. The fluid intake is maintained by saline given subcutaneously.

These are the usual and accepted methods of treatment and without minimizing their importance, I believe the proper management of the altered metab-

olism offers the patient more in the way of beneficial therapy than repeated enemas and hot packs.

We try to anticipate this complication in every abdominal case and knowing that the first change to occur is a decrease in the blood chlorides, we order normal saline by rectum as soon as the patient is sufficiently conscious to retain the rectal tube. This procedure is routine in all my cases and I believe it to be of immeasurable value. By doing this the chloride level of the blood is maintained and the first step in a serious metabolic complex is avoided.

If the blood chlorides are maintained the non-protein nitrogen will not rise and there will not be the same tendency to alkalosis. This point gives me an opportunity to condemn the giving of sodium bicarbonate by rectum on the theory that it prevents acidosis. These patients are already suffering from an alkalosis, why add to the condition by giving more alkali?

These simple procedures will save many cases from more serious complications but the condition is often advanced when brought to us. Fortunately other measures are still at our disposal. Attempts have recently been made to isolate the actual death dealing agent in intestinal stasis. These findings have confirmed what we have long suspected clinically, namely, that the higher up in the intestinal tract the stasis occurs, the more fatal and more rapid is its course. This is especially true in the region of the duodenum. Whether the poison is a toxin secreted by the duodenum mucosa or whether it is in the nature of a proteose remains to be seen. The essential feature is that it is elaborated high up in the intestinal tract and this furnishes the rationale for our so-called duodenal drainage.

As mentioned before many of these patients do not vomit. There is no forward or backward movement of intestinal contents and the disturbed mechanism is furnished with no other alternative than the absorption of these toxic products.

We have, then, the indications for their removal and while gastric lavages may help if done repeatedly, it is annoying to the patient and surgeon alike and for this reason is too often postponed.

I believe a far better procedure is to insert a small rubber duodenal tube through the patient's nose into the stomach and duodenum and by the principle of syphonage institute continuous drainage. The outer end of this tube must be kept lower than the stomach and can be fastened to a bottle at the side of the bed. The tube may be kept in place for several days and during this period the patient is allowed to take water by mouth as desired. The water temporarily satisfies his craving for fluids, dilutes the toxic secretions and with the aid of the tube favors continuous drainage. The nurse is furnished with a piston syringe and, if necessary, keeps the lumen of the tube open by occasionally forcing salt solution into the duodenum. This can be done and the patient not awakened.

We very rarely now perform a jejunostomy in these cases, preferring the use of the duodenal tube, and in my opinion obtaining better results with less danger to the patient. We have had no experience in the treatment of these cases by any serum, and while these may be of some value, their employment is as yet in the experimental stage, and the reports of their use are not very encouraging. Nor have we had experience with spinal anesthesia, as recommended by Mayer in 1922, and would rather advise against it as the risk incurred does not seem commensurate with the advantages which are claimed for this course of treatment.

I would like here to report briefly three cases in which we have used this treatment.

CASE HISTORIES

CASE I. J. S., aged sixty, pyloric stenosis. Physical examination before operation showed patient normal for a man of his years. Blood pressure 160/90.

Operation: Posterior gastroenterostomy. No particular difficulty about operation.

Patient did well for forty-eight hours, no nausea or vomiting, or even gastric distress; temperature and pulse normal. At the end of forty-eight hours, slight rise in temperature and pulse. Abdomen, especially in the epigastric region, slightly distended. Enema relieved distention. Non-protein nitrogen 50. At the end of the following twenty-four hours the patient commenced to have hiccoughs with feelings of nausea though no actual vomiting. But the epigastric region commenced to show that distended condition which obtains in acute dilatation of the stomach.

It was very evident that the patient was developing a case of acute dilatation of the stomach. The Levine tube was inserted through the right nostril and gastric drainage and lavage begun. The patient remained in about the same condition for three days when he gradually improved and made a good recovery. The drainage recovered 134 oz. during twenty-four hours. This patient also for the first few days felt so comfortable with the tube in that whenever it was removed, he begged to have it replaced. The tube remained in the duodenum for ten days. I am of the opinion that the use of this tube in this case, and with the continuous drainage which it maintained, saved his life.

CASE II. Mrs. S. E., aged fifty-eight, acute appendix.

Patient did very nicely for twenty-four hours when temperature and pulse began to rise and abdomen to distend. Levine tube immediately introduced into duodenum and large amounts of fluid, finally becoming fecal in character, recovered.

Patient died at the end of another forty-eight hours and at autopsy nothing abnormal was found save a few coils of distended intestine. There was no mechanical obstruction, no peritonitis and the appendicular wound was nicely healed. This was surely then a case of paralytic ileus but from what cause was never determined and while the use of the Levine tube made the patient much more comfortable it did not save her life.

CASE III. J. N. aged forty-five, interval operation for a chronic appendix (usual operation).

Good convalescence for forty-eight hours when signs of a paralytic ileus began to develop. Rise in temperature and pulse, gradually

distention of abdomen, soft in character, not hard as in peritonitis, and some feeling of nausea. N.P.N. 40.

Levine tube was immediately inserted and left in for forty-eight hours. Drainage at first was bile stained, then bile and then frankly fecal. Stomach was washed out every six hours with plain water and at end of forty-eight hours drainage became less fecal in character, and patient passed some flatus per rectum. Patient was then fed small quantities through tube which was retained. Tube was permanently removed at end of another twenty-four hours and from then on patient made an uneventful recovery and has remained well ever since, two years.

In this case there was no mechanical obstruction because there was no tumor mass to be felt and no reverse peristaltic movements of the bowels.

The technique of this method has been worked out by my assistant, Dr. Nelms, and myself; in fact he first suggested the procedure to me and should be given much credit.

So far my colleagues and I have had 15 cases of abdominal distention in which I

have used this method; 10 of these have recovered and 5 have died. But I am firmly convinced that of the 10 who lived, 5 at least would have died by the ordinary treatment of jejunostomy, etc.

Some years ago Dr. Willy Meyer wrote an article on this subject in which he advocated the use of a tube somewhat larger than the Levine tube, but not in the same way as I have outlined here.

In conclusion I make a plea for more conservatism in abdominal operations and wish to emphasize the fact that post-operative distention of the abdomen is most always accompanied by intestinal stasis. As a result of this stasis we have absorption of intestinal contents resulting in the metabolic triad of low blood chlorides, high non-protein nitrogen and an increase in the carbon dioxide combining power of the blood plasma. The indications, therefore, are to maintain the blood chlorides by vigorous chloride therapy and to remove the toxic intestinal contents by continuous duodenal drainage.

DIAGNOSIS & TREATMENT OF
ACUTE INTESTINAL OBSTRUCTION
INVOLVING THE SMALL INTESTINE*

BYRD CHARLES WILLIS, M.D., F.A.C.S.

ROCKY MOUNT, N. C.

THIS paper is limited to the consideration of acute small bowel obstruction, the early diagnosis of which is of great importance in saving human life.

Haggard¹ quoting Sir William Taylor states: "The mortality in primary acute intestinal obstruction is nearer 60 per cent than it is 35 or 40 per cent, as usually given." The cause, type or location of obstruction in small bowel, whether simple or strangulated, seem to make little difference in the symptoms, but does influence the rapidity and gravity of the disease. The early symptoms that should lead to a probable diagnosis are abdominal pain, nausea, vomiting, prostration, early pulse and temperature normal, temperature sometimes subnormal. The pain may follow a period of discomfort and general depression. The character of the pain is of great importance. Peristaltic pains are rhythmic, increasing in intensity and coming at regular intervals, with short periods of relief for the first twelve or twenty-four hours, when paresis may set in, pains gradually disappearing, followed by abdominal distention, periodic vomiting, cold, leaky skin, rapid and weak pulse. The pain is usually around the umbilicus or epigastrium. With epigastric pain, we realize the importance of ruling out coronary disease in patients over forty years of age and have it differentiated when necessary by an electrocardiogram. Nausea is very transient and is of less significance than vomiting. The first vomiting is projectile, with rapid emptying of stomach contents, and unless fluids are withheld, bile, followed by stercoraceous material, is expelled. The extent of pros-

tration depends upon the amount of vomiting, violence of pain, and the presence of actual strangulation with vascular disturbance. The important matter is to recognize the obstruction, withhold devastating purges and seek early operative relief. The textbooks give a very full symptomatology, and when all of these are present the patient is in extremis. It is important to know the early signs of intestinal obstruction. The triad of obstipation, vomiting, and rhythmic abdominal pains is sufficient on which to base an early diagnosis, especially in a patient previously operated upon abdominally or who has an old hernia. The vomiting and the colicky abdominal pains should excite suspicion; repeated enemas, two or three, the last two without results, confirm the diagnosis. It is a pity that enemas cannot be popularized and given in pill form with as much ease as are purges, for thereby the mortality in acute abdominal diseases would be greatly reduced. It is better to explore an abdomen and find it negative than not to explore and find obstruction at autopsy.

Dr. C. T. Smith, of Park View Hospital, in a recent paper before the Fourth District Medical Society, summarizes the urine and blood findings in obstruction as follows: "The presence of albumin, casts, and blood in the urine are fairly constant findings in acute intestinal obstruction. The blood urea will increase after twenty-four hours, and a persistent rise makes the prognosis grave. The total leucocyte count is apt to be misleading. The differential polymorphonuclear count is more reliable." He further states, "The

* From the Surgical Service Park View Hospital. Read before the general session of the North Carolina Medical Association, Greensboro, N. C., April 19, 1929.

temperature, pulse and blood pressure form no criterion as to the illness of the patient or his chance of possible surgical recovery."

In the past fifteen years 134 patients suffering with acute small bowel intestinal obstruction have been admitted to Park View Hospital to the service of Drs. Boice and Willis and operated upon by both or one of them. It is more imperative to operate upon these patients as soon as the diagnosis is made than in acute appendicitis; many operations were performed around and after midnight. Twenty two, 16 per cent, of these died following operation, 2 of them on the operating table. None was denied operation, no matter how desperate the condition. We have further divided the deaths into institutional, in the hospital forty-eight hours, and non-institutional, under forty-eight hours. Fourteen died after forty-eight hours (institutional deaths) and 8, under forty-eight hours (non-institutional deaths). Forty-two of these patients were enterostomized, and among these, 17 of the deaths occurred. The high death rate in this class of case is probably due to their more desperate condition. Six had simple enterostomy with aspiration of bowel content and immediate closure of opening in bowel. One of these died.

The immediate anatomical cause of the obstruction was a band or bands in 39, adhesions in 31, intussusception in 3, femoral hernia in 7, inguinal hernia in 46, paresis in 2, stricture perforation in 2, simple stricture 1, caught in appendix abscess wall 3. Fifty-seven of these 134 patients had been operated upon abdominally; 43 of the 57 had been operated upon from months to years previously, and 14 were still in the hospital when the obstruction developed. Nearly 42 per cent had been operated upon abdominally. Ninety-six, 71 per cent, of these 134 obstruction cases had either been operated upon abdominally or had herniae, the latter containing partially strangulated small bowel. There were 3 deaths among

the 46 incarcerated small bowel inguinal herniae, and 1 death in the 7 femoral herniae. The mortality was 7.5 per cent in the inguinal and femoral hernia patients. In 10 patients it was necessary to resect or repair the bowel.

It is difficult to say definitely just when complete obstruction takes place in any patient. Symptoms may be present but obstruction not occur for many hours after onset. We have assumed that the obstruction began with the beginning of symptoms. In the case of incarcerated small bowel in hernia it is fairly accurate to date the time from descent into hernia.

According to the time elapsing between beginning of symptoms and operation, the deaths in the various periods were as follows:

| | Cases | Deaths |
|-------------------------|-------|--------|
| Less than 24 hours..... | 27 | 1 |
| 24 to 48 hours..... | 43 | 5 |
| 48 to 72 hours..... | 14 | 6 |
| Over 72 hours..... | 27 | 8 |
| Time not recorded..... | 23 | 2 |

Among those that were enterostomized the deaths in similar periods were as follows:

| | Cases | Deaths |
|-------------------------|-------|--------|
| Less than 24 hours..... | 3 | 0 |
| 24 to 48 hours..... | 14 | 6 |
| 48 to 72 hours..... | 9 | 4 |
| Over 72 hours..... | 15 | 7 |
| Time not recorded..... | 1 | 0 |

The treatment of all these cases has been similar because my associate, Dr. E. S. Boice, and I many years ago arrived at the opinion that these patients needed normal saline early and in large amounts. They did not do well if allowed water by mouth. Our first enterostomy was done in 1919 to evacuate the large amount of liquid feces above an obstruction. We decided to sew in the catheter for drainage. This was largely empirical treatment, but its virtues and the correctness of our observations have been proved by the splendid work of Orr and Haden,² Foster,³ Foster and Hausler,⁴ McIver and Gambel,⁵ Trusler,⁶ McVicar and Weir,⁷ and others, in their recent experimental and

chemical studies in obstruction. We have added dextrose solution intravenously and rectally, but otherwise have made no change in treatment for years.

Foster divides obstruction simply into two classes, as follows: (1) "Such cases as bands and adhesions which cause acute simple obstruction of the continuity of the gastrointestinal tract without primary vascular derangement; (2) Those, such as volvulus, incarcerated herniae, and intussusception, in which there is a variable length of intestine obstructed as well as an interference of the vascular supply to it." This second group he has called acute intestinal strangulation. We consider this a very simple, satisfactory and workable classification.

The essential treatment of all obstruction, in our opinion, is to combat the dehydration, the loss of sodium chloride, the resulting alkalosis, rarely acidosis, the toxemia from strangulation, the kidney depression and finally, to reestablish bowel continuity. Operation is performed immediately unless the patient is too ill, when time should be taken for giving dextrose saline solution and the application of heat to improve the general condition. This can often be done while preparations are being made in the operating room.

Subcutaneous or intravenous administration of normal or of 2 per cent saline (intravenously) in 3000 c.c. of water given in twelve hours, 1000 c.c. doses at four-hour intervals, will overcome the dehydration, and reestablish the sodium and chloride ion balance which, in turn, successfully combats the alkalosis. If 100 gm. of dextrose are added to each 1000 c.c. of saline solution, the kidney depression will be overcome unless the kidneys have been greatly damaged. In giving the combined saline dextrose solution of this strength, it is necessary to administer it intravenously. Saline dextrose by rectum is used chiefly to cleanse the bowel. Its retention and absorption by the bowel is too uncertain to risk the life of the patient.

We start the subcutaneous use of saline simultaneously with the operation.

Next in importance is the choice of anesthetic. This should be governed by the general condition of the patient and by the mechanical difficulties present, such as obesity and deep pelvic location. We have long recognized that the intra-abdominal obstruction cases of the same duration are more desperately ill than are those of incarcerated hernia which we classify as extra-abdominal. The reason for this we do not know unless it is due to the tightly constricting ring preventing the peritoneal absorption of the products of decomposition secondary to strangulation. We think the following case shows the lack of peritoneal absorption:

A robust colored man, aged twenty-six, previously in good health, entered with large strangulated hernia of sixteen hours' duration. Temperature 98.2°, pulse 82, systolic blood pressure 140, leucocyte count 8000, blood urea 45. At operation he was found to have 6 feet, 8 inches of strangulated gangrenous bowel composed of ileum and cecum with their mesentery. On making incision through skin, there was distinct odor and discoloration of underlying tissue. When the sac was opened, dark bloody fluid with very offensive odor escaped. The bowel was hopelessly gangrenous. Since the patient's condition seemed favorable, resection was thought feasible. A second low, right rectus, abdominal incision was made, cavity walled off, strangulated bowel released, and, to our great surprise, patient went into profound shock and died on the table before resection could be completed. Saline had been started as usual, and he was under ether anesthesia. We attributed his death to unknown toxin or histamine.

For all desperate cases and elderly persons, we use local anesthesia, sometimes supplemented by gas-oxygen; for others, ethylene or ether. We do not favor a high enterostomy without the release of the obstruction. In 2 cases in which we did this the patient died. Large quantities of material were drained off through the enterostomies but the patients never rallied sufficiently to warrant a second operation.

Postmortem showed one to have a simple band, and the other, short intussusception, the release of which would have added very little to the operative risk. Forty enterostomies were done upon the intra-abdominally obstructed, while only two extra-abdominally obstructed (herniae) were so treated, yet in many of the latter the bowel was apparently damaged as much as in the intra-abdominal obstructions.

The incision is made at the point most serviceable for releasing the obstruction, which is done with as little trauma and as rapidly as possible. The enterostomy should be located in healthy bowel about 10 or 12 inches above the obstruction, using two rows of simple purse string sutures, the first of which is passed through the tube, attaching it to bowel. It is important, on opening the bowel, to introduce a suction tube, and quickly and gently evacuate the contents of the bowel, passing the aspiration up and down the lumen. We agree with others that this material should not be allowed to enter the collapsed, "thirsty" bowel below the point of obstruction. Making the enterostomy opening in the greatly distended bowel, thus reducing the abdominal contents, often facilitates finding the cause of intra-abdominal obstruction. In a few cases several openings were made and closed immediately after aspiration. The enterostomy tube is brought out at either end of the incision or through a stab wound, following the Mayo method in the use of omentum about the tube. Following operation the bowel is irrigated with 2 per cent salt solution, oz. 2, every two hours during the next forty-eight hours. Morphine should be given in sufficient quantity to quiet peristalsis and patient.

Cardiac and respiratory stimulants such as epinephrin, ephedrine, coramine, atropine, large doses of caffein sodium benzoate, and others are given as indicated.

Gastric lavages are done when there is much vomiting. Fluids by mouth are withheld for twenty-four to forty-eight hours, and longer if indicated. These patients should receive large quantities of fluids, 3000 to 5000 c.c., subcutaneously or intravenously. Disagreeable gastric lavage, except at the time of operation, is no longer a necessity when obstructions have been released, oral fluids withheld and subcutaneous saline given in the amounts here stated.

SUMMARY

The factors of importance in acute intestinal obstruction are:

1. Early recognition of acute intestinal obstruction which offers the greatest hope for lowering the mortality.
2. The application of modern treatment, on the basis of our newer knowledge, to overcome the dehydration, alkalosis and kidney depression.
3. Proper selection of anesthetic for the individual case.
4. The judicious use of enterostomy in the healthy bowel above the obstruction, and not the empirical use of high jejunostomy.

MEATOTOMY WITH SUTURE OF CUT EDGES OF SKIN & MUCOUS MEMBRANE*

EDGAR G. BALLENGER, M.D., F.A.C.S., OMAR F. ELDER, M.D. AND

HAROLD P. McDONALD, M.D.

ATLANTA, GA.

MEATOTOMY, although a minor operation, is frequently neglected and often crudely done. A small meatus, 26 F. or less, should be incised when one or more of the following indications exist: non specific urethritis, unusually persistent or recurrent specific or non-specific urethritis, frequency of urination or other urinary disturbances, for diagnosis and treatment of stricture, both congenital and acquired, for cystoscopy and cysto-urethroscopic investigations, and to lessen the tendency to hernia in boys when the meatus is very small. Hernia has been noticed in boys with a small meatus sufficiently often to lead us to think that it acts as a causative factor.

The usual method of performing a meatotomy is simply cutting the meatus under local anesthesia to the desired size, usually 30 or 32 F. Some operators then wrap the penis with gauze and a bandage, and subsequently open the meatus with large sounds every few days to prevent the cut edges from healing together. Others apply Monsell's solution, concentrated silver nitrate or such agents to the cut surface to check bleeding, lessen pain on voiding and prevent the healing without the necessity of sounds.

Among the disadvantages of meatotomy as performed in the usual way are:

1. The painful tearing apart every day or so by sounds to prevent the edges from healing again.

2. Hemorrhage is sometimes an annoying feature in ordinary meatotomy operations when caustic agents are not employed; this is usually more annoying to the patient than to the surgeon.

3. The result is often not a normal-looking meatus.

4. In those instances where caustic agents are used there is a tendency to contraction and later constrictions of the meatus.

FIG. 1. Meatotomy. Inserts show method of closing mucosa to skin using uncut sutures as retractors to facilitate introduction of lower sutures.

5. Not infrequently there is spraying of the urine.

In order to overcome these disadvantages of meatotomy, as ordinarily performed, we began some time ago to suture the cut edges of the skin and mucous membrane with ten day, 00 chromic catgut. Since the adoption of this technique we have performed 119 meatotomies with results so satisfactory and so free from the usual disadvantages of the other methods that we are still enthusiastic about the suture method of meatotomy.

TECHNIQUE

Preliminary to the injections of novocaine about $\frac{1}{2}$ oz. of a 1 or 2 per cent. solution of novocaine is injected into the urethra and held for two or three minutes. This partially anesthetizes the mucous membrane so that the needle puncture

can be made just on the inside of the meatus through the mucous membrane with less pain than through the skin. One of two drops of adrenalin solution is added to the novocaine to lessen the bleeding at the time of the operation and thus facilitate suture. After the incision is made, the first sutures are placed at the outer edges of the cut, catching only the skin and mucous membrane in the sutures. Reaching the deeper part of the mucous membrane is made easier by temporarily leaving the 2nd or 3rd stitches long and using them as retractors to open up the meatus and expose the inner margin of the mucous membrane. (See Fig. 1.)

In our experience, meatotomy performed in this way is definitely superior to the other methods. The operation

requires five or ten minutes longer, but the final results more than justify this slightly longer time. Occasionally the shape of the glans penis and meatus make it desirable to cut the upper, not the lower, part of the meatus.

The advantages of this method are:

1. Healing is more prompt.
2. There is no necessity of passage of sounds to keep the meatus open while healing.
3. There is less pain and practically no hemorrhage.
4. There is no tendency to become narrow again as with the usual methods.
5. After the absorption of the sutures there is no spraying of urine.
6. The cosmetic and final results are better.

SODIUM ISO-AMYL-ETHYL BARBITURATE

SODIUM AMYTAL IN THE PRELIMINARY PREPARATION OF PATIENTS FOR REGIONAL ANESTHESIA*

J. T. C. McCALLUM, M.D. AND L. G. ZERFAS, M.D.

INDIANAPOLIS, INDIANA

THE increasing use of procaine for regional anesthesia is the result of improved technic in nerve blocking, better control of subdural anesthesia, and a general desire on the part of anesthetists and surgeons to avoid inhalation anesthesia when possible. It follows that larger quantities of procaine are being used, for example, in nerve blocking, and that the toxic manifestation occasionally observed from the use of this drug may become increasingly important.

Tatum, Collins and Atkinson,¹ and others have demonstrated the value of barbital in preventing acute cocaine intoxication in animals, and Loevenhart² and his associates have shown that the acute intoxication in animals resulting from procaine may be prevented by the use of barbital or sodium iso-amyl-ethyl barbiturate (sodium amytal). Isenberger³ and his associates concluded from their work on dogs at the Mayo Clinic that sodium iso-amyl-ethyl barbiturate protected against convulsions resulting from the use of procaine, but that it did not prevent the depression brought about by overwhelming doses of procaine. They found that "the combination of iso-amyl-ethyl barbiturate or other safe barbituric acid hypnotic, with properly controlled ventilation, offers the greatest hope for the saving of life in cases of severe poisoning by procaine."

Beside the toxic manifestations occasionally observed from the use of procaine, there is the disadvantage of the psychic trauma associated with the operation. The average patient prefers to know little or nothing about the operative procedure; therefore, it becomes important to prepare the patient more carefully than when a general anesthetic is to be given.

Lundy⁴ has reported the use of sodium iso-amyl-ethyl barbiturate in combination with other preliminary medication in 730 surgical cases. In these, there was little, if any, delirium; nausea rarely occurred, and there were no respiratory difficulties. He considered preliminary medication employed brought the patient to the operating room with a good mental attitude toward local anesthesia whether the patient had favored it prior to the operation or not.

In previous publications⁵ we have discussed at length the use of sodium iso-amyl-ethyl barbiturate in surgical and non-surgical cases. Drabkin⁶ and his associates, Weiss⁷ and others⁸ have also reported their experiences with the use of barbituric acid derivatives used in man for a variety of conditions. It is the purpose of this publication to report our experiences with a small series of surgical cases in which sodium iso-amyl-ethyl barbiturate was given prior to the local infiltration of the tissues with procaine.

PREPARATION OF THE DRUG

Sodium iso-amyl-ethyl barbiturate is prepared in a pure anhydrous form, and, when sealed in glass vessels for protection against moisture and carbon dioxide, a perfectly stable compound is assured, even when subjected to severe durability tests.

The hydrogen-ion concentration of the preparation is adjusted so that a 10 per cent solution in triple distilled water will show pH values ranging between 9.5 and 9.8. On animals this pH range has given the maximum anesthetic effect with a minimum degree of toxicity. These points, we feel, are important when the drug is to be injected into the blood stream.

* From The Lilly Laboratory for Clinical Research, Indianapolis City Hospital. Submitted for publication December 13, 1929.

ADMINISTRATION AND DOSAGE

Sodium iso-amyl-ethyl barbiturate may be administered by mouth, rectally, intramuscularly or intravenously. For rectal, intramuscular or intravenous injection, the drug is prepared by adding the anhydrous sodium salt to triple distilled sterile water, making a 10 per cent solution. The sodium salt should be thoroughly dissolved by gentle agitation, and the resulting solution should be essentially water clear. Solutions which are opalescent should be discarded, and a clear solution should not be allowed to stand exposed to the air for any great length of time if it is to be used for intravenous injection. The rate of intravenous administration should not exceed 1 c.c. per minute.

The patients were observed closely during the period of slow administration for their reaction to the drug. This individual reaction gave, in our opinion, the most valuable indication of the correct dosage required for the patient. As a rule, the patients went to sleep after the administration of from 0.3 to 0.5 grams ($4\frac{1}{2}$ to $7\frac{1}{2}$ grains), though occasionally a patient required more or less than that amount. The dosage that induced profound sleep, the solution being given at a uniform rate, was a guide to the amount of the drug required to produce a desired effect. In a few patients the intravenous dosage was limited to the amount that would produce drowsiness without inhibiting cooperation.

When only mild sedative effects, and when cooperation of the patient is desired, the drug may be given orally the night before in doses of 0.2 to 0.3 gram (3 to $4\frac{1}{2}$ grains) in about 15 c.c. of water and repeated one-half to one hour before the time of operation. It is better, however, to administer it in capsules as the drug is very bitter to taste.

The dosage of sodium iso-amyl-ethyl barbiturate varied from 7 to 20 mg. per kilogram of body weight. Apparently, however, there is only a very approximate relationship between body weight and dosage. The age, nervous temperament,

metabolic rate and the physical condition of the patient are factors of such importance as to render impracticable any attempt to grade dosage entirely on body weight.

Children and adults with hyperthyroidism required more than the normal adult in proportion to their weight. Patients of a very nervous temperament required larger doses than the average, while apathetic individuals reacted to smaller doses. Elderly persons and those whose resistance had been lowered by chronic illness or who were on the verge of shock, reacted to considerably smaller doses of the drug than did vigorous, healthy individuals.

Irrespective of these various factors, however, some persons without any evidence of idiosyncrasy to the drug were apparently more susceptible to the effect of sodium iso-amyl-ethyl barbiturate than were others; hence, the fundamental importance of careful and intelligent observation during a period of slow administration of the drug.

When given by mouth or by rectum, the rate of absorption makes it difficult to obtain exactly the effect desired, when needed, without giving more or less of the drug than is required. If one gives doses by mouth, rectally, or intramuscularly, large enough to produce unconsciousness, one can never be certain that a continued absorption of the drug may not occur for some time afterwards, thus leading to a prolonged cumulative action. It is possible to produce a cumulative action in man by giving repeated intravenous injections before the initial and subsequent amounts of the drug are eliminated, or it is possible to overwhelm the patient with a single large injection. One can demonstrate this with any of the inhalation anesthetics, especially ether and other less volatile anesthetics.

If loss of consciousness is desired, in our opinion, the safest and most satisfactory manner is to administer the drug intravenously. By carefully watching the patient during the time the drug is being

injected, one is able to control the dosage as the effects of the drug are obtained almost immediately and the results are more uniform. The rate of absorption then becomes a negligible factor, and, in addition, one obtains the peak effect of the drug when needed. It has also been our experience that patients regain consciousness much sooner after the intravenous injection of the drug than they do when the same amount is given by mouth, per rectum or intramuscularly.

GENERAL EFFECTS

The general effects refer chiefly to those observed during and after the intravenous injection of the drug. During the time of injection observations were made relative to blood pressure, mental reaction, rate and amplitude of the respirations, and color of the skin. Within three to five minutes after the intravenous injection was begun, the patients became drowsy. Shortly thereafter they fell into a profound sleep, often developing a snoring type of respiration. As a rule the patients were carried rapidly through the first stages of anesthesia so that excitement, laryngospasm, nausea and vomiting were rarely observed. Many of the patients lost consciousness in the midst of an incomplete sentence.

The pupils were usually slightly constricted or normal in size. The gag reflex was present in essentially all instances. The knee jerks were absent in this stage, and there was slight dilatation of the rectal sphincters. The skin reflex was practically never absent. The degree of muscular relaxation varied with different individuals, but was rarely complete with the administration of 1.0 gram (15 grains). The respirations following the loss of consciousness were usually decreased in amplitude, were regular, and were apt to be slightly increased in rate, though frequently they remained normal. There was little change in the color of the skin, although occasionally a slight degree of cyanosis or considerable blanching occurred.

EFFECTS ON PULSE RATE AND BLOOD PRESSURE

The pulse rate during and shortly after the completion of the injection varied somewhat. The rate was usually increased, was very seldom decreased, and often it was unchanged from normal. The pulse volume decreased during the time the temporary fall in blood pressure occurred.

The blood pressure nearly always decreased during the time the drug was being injected, but, as a rule, it returned to its previous level within a few minutes. In a recent publication,⁵ charts illustrating this fall in blood pressure were presented. This temporary decrease in blood pressure usually amounted to 20 to 30 mm. of mercury. Marked decreases in blood pressure have been observed in patients with hypertension, elderly people with arteriosclerosis, and in patients with unstable cardiovascular systems. In these types of patients, it is an advantage to determine this while injecting the drug intravenously, so that the further administration of the drug may be discontinued.

METABOLIC EFFECTS

It has been shown in a previous publication⁵ that there is a negligible change in blood sugar, CO₂ combining power and non-protein nitrogen. Also, urine examinations were essentially normal except for a trace of acetone and a slight decrease in the twenty-four hour volume output for the first few days after the operation. These observations were made when the amount of sodium iso-amyl-ethyl barbiturate administered was sufficient to produce general anesthesia uncomplimented by other anesthetics.

The small series of surgical cases reported here includes the following types of operation: Laparotomy 31, otolaryngology 9, thyroidectomy 6, rib resection 4, and prostatectomy 2. The average amount of sodium iso-amyl-ethyl barbiturate administered intravenously prior to the local infiltration of the skin and deep

tissues ranged between 0.3 and 1.1 grams ($4\frac{1}{2}$ to $16\frac{1}{2}$ grains).

OBSERVATIONS

In 29 patients, there was an absence of any sign of stimulation during the period of operation. Slight stimulation manifested by movement of the hands and feet occurred in 15 patients. Restraint of the arms and legs was found necessary to avoid contamination of the operative field in 6 cases; while 2 patients reacted to such a degree that nitrous oxide and oxygen or ether was given in order to proceed with the operation. Patients whose sleep was induced with sodium iso-amyl-ethyl barbiturate and who became restless during operative procedures so that in some instances they talked incoherently, on awakening recollected nothing that occurred during the time of operation.

It was further observed that unless the dose of the drug was moderately large, the degree of muscular relaxation approximated that obtained when local anesthesia was used alone. In those patients where there was a definite reaction to stimulation, a decided muscular resistance was present.

DISCUSSION

The combined use of sodium iso-amyl-ethyl barbiturate and procaine anesthesia gave satisfactory results in approximately 50 per cent of the cases. The patients were asleep and were relieved of excitement; especially was this sleep beneficial in operative procedures in children where the surgeon desired to use local anesthesia. It proved to be an aid to the surgeon, and freed the patient from the apprehension and mental trauma, which, as a rule, contraindicates the use of local anesthetic agents in children. A similar advantage was experienced in its use in the apprehensive and nervous adult patients.

Five patients, almost in a condition of shock from intestinal obstruction, hemorrhage, or trauma, were successfully operated under an anesthetic of from 0.3 to

0.5 grams ($4\frac{1}{2}$ to $7\frac{1}{2}$ grains) of sodium iso-amyl-ethyl barbiturate intravenously and procaine locally.

The injections of procaine were done by several different men, as were the operations. The injections were not all perfect, and, in some instances, the surgeons were not accustomed to operating with local anesthesia, especially for abdominal work. These variable factors, no doubt, accounted for many of the difficulties experienced. On the other hand, there were a few patients who reacted after what seemed to be perfect injections of procaine. These cases suggested the possibility that sodium iso-amyl-ethyl barbiturate may have interfered in some manner with the effectiveness of the procaine anesthesia. This point is being investigated further.

Greater nursing care was found to be necessary for several hours following the time of operation when this type of anesthesia was used. This was especially so when doses of 1.0 gram (15 grains), or larger, were employed. The patients not only slept for several hours after the operation, but were more apt to be restless and temporarily disorientated on awakening. In our experience it has been preferable to employ the various methods of general or spinal anesthesia rather than to give comparatively large doses of sodium iso-amyl-ethyl barbiturate intravenously in combination with local infiltration of the tissues with procaine.

We are of the opinion that for sedative effects the administration of 0.3 to 0.5 grains ($4\frac{1}{2}$ to $7\frac{1}{2}$ grains) of sodium iso-amyl-ethyl barbiturate combined with $\frac{1}{8}$ to $\frac{1}{4}$ grain of morphine, given one-half to one hour prior to the local injection of procaine, is most satisfactory. For those patients who are very apprehensive about the local use of procaine and desire to be unconscious, we advise the intravenous use of the drug. Just enough should be given to produce a sound sleep. This amount seldom exceeds 1.0 gram (15 grains).

SUMMARY

1. Sodium iso-amyl-ethyl barbiturate, when used intravenously or orally with morphine ($\frac{1}{6}$ to $\frac{1}{4}$ grain, given hypodermically) to produce analgesia and narcosis short of sleep, was a very effective preliminary preparation for local anesthesia.

2. The intravenous injection of sodium iso-amyl-ethyl barbiturate sufficient to produce sound sleep is advised only in those patients who desire to be unconscious or in children and uncooperative patients to whom local anesthesia is to be given.

3. It is seldom necessary to give adult patients more than 1.0 gram (15 grains) of the drug at one time to produce profound narcosis.

4. The drug, prepared in a 10 per cent solution, when administered intravenously, should be given at the rate of approximately 1 c.c. per minute, with careful observation of the patient during the time of the injection. By this means one is able to more or less control the dosage.

5. Sodium iso-amyl-ethyl barbiturate acts as a prophylactic measure in counteracting the toxic manifestations of procaine occasionally observed when local anesthesia is employed.

POINTS IN THE QUARANTINE IN ABDOMINAL SURGERY*

J. F. BALDWIN, M.D.

COLUMBUS, O.

THE excellent argument by Dr. Robert C. Coffey,¹ on protecting the peritoneal cavity from local infection, merits the careful study of every surgeon.

There are three maneuvers which, with the same object in view, I have been employing for very many years and with the utmost satisfaction:

1. In dealing with an infected gall bladder, whether tube or cigaret drainage is necessary, the omentum is pulled up and tucked in below the liver and the drain, a stitch or two being inserted to keep it from becoming displaced. This disposition of the omentum "quarantines" the general peritoneal cavity, and at the same time obviates the formation of adhesions between the liver and bowel which sometimes prove serious.

2. In making appendicitis operations, in cases in which drainage will probably be necessary, a right rectus incision is made, through which, after protecting by a cofferdam of sponges, the appendix is removed and the abscess mechanically cleaned. A stab incision is then made well over in the general region of the anterior superior spinous process, the location of the stab being determined by the fingers on the inside so as to have the drain at the best possible point for reaching the abscess cavity. The stab opening is made by making a skin incision about 1 inch in length, parallel with the fibers of the external oblique, through which is forced a pair of sharp-pointed scissors; the scissors are then partly opened so as to enlarge sufficiently the drainage track. A hemostat is passed along the side of the scissors and the ends of the ligatures,

which have been used on the meso-appendix and the appendix stump, are caught and withdrawn. The hemostat is again introduced and one end of the drain is withdrawn carefully, together with the scissors, so that the far end of the drain can be nicely placed in the pus cavity. With the inside fingers the cecum is pushed well over to the right, aided by slight traction on the protruding ligatures. The cofferdam is withdrawn, the omentum brought over so as to protect the general cavity more completely, the main incision closed in layers as usual, and a single silkworm-gut stitch so inserted in the skin at one end of the stab incision as to catch the protruding ligatures and drain. In case the infection has extended into the pelvis, the drain is extended to the bottom of the culdesac and still by proper manipulation it can almost invariably be so placed as to avoid contact with the small bowel, and thus obviate postoperative ileus. The drain is a dressed tube or a cigaret of gauze and tissue as indicated.

The patient is encouraged sometimes to lie on the right side for a few hours, but that is probably unimportant. There seems to be no tendency whatever for the omentum or cecum to pull away from the site of the drainage. The drain is usually removed in five to seven days. The catgut ligatures come away of themselves. The unavoidable contact of the necrotic appendix and of the pus with the subcutaneous fatty tissue of the abdominal incision usually results in its infection, but when the stitches are left undisturbed, as advised several years ago by Graham, of Chicago, the pus usually finds its way out between the stitches and healing takes place very satisfactorily, though sometimes slowly. Occasionally, however, it becomes necessary to remove the stitches, or part of

¹ Application of the principle of the quarantine in abdominal surgery. *Ann. Surg.*, 85: 808, 1927.

The quarantine in abdominal surgery. *AM. J. SURG.*, n.s. 6: 593, 1929.

* Submitted for publication June 19, 1929.

them, to get better drainage, but this usually results in the later necessity of curetting and sterilizing the exposed surfaces and re-inserting stitches to bring them into apposition.

3. This is the most important of all, and has given me many successful results which would not otherwise have been obtained:

In cases in which removal of the uterus and its appendages leaves the denuded pelvis the seat of extensive infection, the round ligaments are implanted in the vault of the vagina as usual, the posterior wall of the vagina split down to about the bottom of the culdesac, the distal ends of two or three strips of washed iodoform gauze introduced into the vagina and the rest of the strips made into a fluff lightly filling the pelvic cavity. (If it has been possible to save the ovaries, these are attached pretty high up on each side so as to be out of the way of future trouble, since if allowed to drop into the culdesac they will frequently prove a source of pronounced dyspareunia.) The sigmoid is then swung around over the gauze and attached with continuous catgut to the margin of the healthy peritoneum, so as to make a complete roof to the pelvis. Over this the omentum is then pulled down so as to protect still further. There has thus been secured a very complete partition between the infected pelvis and the uninfected abdominal cavity. In attaching the sigmoid the stitches are inserted so as to catch some of the fibers of one of the longitudinal bands or the tissues of the mesosigmoid, being careful to avoid the vessels, or some of the appendices epiploicae can be utilized. It is so attached as to cover all the raw surfaces. In rare cases the sigmoid may be so short as to

require mobilization of the cecum in order to complete the partition by attaching the two together.

This mobilization of the sigmoid was advised by a western surgeon a good many years ago, but his name I do not recall. I have never seen it used by anyone except myself; but it is one of the most valuable maneuvers that I know of to secure the desired end. I have found it particularly valuable in those cases of puerperal infection with thrombophlebitis in which the uterus is removed and the infected pelvic veins left wide open for drainage. Within a very few hours adhesions form, making the protection perfect. The mobilized sigmoid is held up by the gauze fluff, which is withdrawn through the vagina at the end of one week. Vaginal douches are used afterwards as needed for cleanliness. The sigmoid gradually settles down and makes a complete covering for the pelvis. Care should be used to avoid any sharp kinks in attaching the sigmoid, but if that is done there would seem to be no danger of postoperative ileus.

In cases in which there is no infection present but as a result of extensive pelvic adhesions from fibroids, ovarian tumors, etc., the pelvic peritoneum has disappeared, the same technique of introducing the fluff and mobilizing the sigmoid has been equally satisfactory in obviating adhesions. If the uterus is to be left, the vagina is opened freely into the culdesac and the gauze strips placed through that opening.

By the technique described I have not for many years had a single case of post-operative ileus, though I have known of the occurrence of many cases in the hands of colleagues who have not employed these methods.

A METHOD OF DRAPING FOR OPERATIONS ON THE NECK*

FREDERICK A. COLLIER, M.D., F.A.C.S.

ANN ARBOR, MICH.

IN operations on the neck, especially thyroidectomy, the operative field is usually isolated from the patient's

tion and storing, it is folded once again in the same direction, bringing points g to c and h to d, thus leaving the "zipper"

FIG. 1. Sheet showing dimensions.

head and the anesthetist by the use of sheets draped on metal hoops of various patterns. In the University Hospital we have used for several years a method of draping that has proved simple, convenient and practical and that offers certain advantages over the usual methods.

The unique feature of this method lies in the use of a sheet 90 in. square, on one side of which are sewed talon fasteners with the eye and lock at one corner and the thread end at the opposite corner, leaving a gap between the fasteners of 12 in., which will pass around the neck (Fig. 1). The talon fasteners are similar to the fastener used on the zipper bags, etc. and come attached to a narrow strip of stout cloth which can be sewed to the usual operating-room sheets. The sheet is folded on itself as shown in Figure 2. In order to reduce it to a compact package suitable for steriliza-

FIG. 2. First fold.

border up. The sides are now folded in accordion pleats toward the center. It can now be wrapped or placed in drums for sterilization. When ready for use, the patient is placed on the table, two sterile towels are placed under his head, the neck and lower face prepared by any desired antiseptic, the upper towel is lifted by the anesthetist and clamped over the forehead to cover the hair and make a cap. The head is now lifted and the sheet folded as in Figure 2, passed under the head, between the towels until the neck lies in the space EF. Points A and B are now lifted up to meet each other above the patient's head, the sheet being kept taut while c and d are dropped to meet the body draping. The fasteners are engaged and by pulling the button to points EF as shown in Figure 3 the upper half of the sheet becomes a wall separating the anesthetist and the patient's head from the operator and his field. The opening for the neck is best left smaller than the patient's neck since the button as it is pulled down can be locked at any desired point when the sheet is snugly around the neck. The upper portion of the drape falls closely over the patient's head and the anesthetist as shown in Figure 4. This gives the operator every

* Submitted for publication June 18, 1929.

opportunity to work from the side. Retraction can be used in any direction and the range of movement and activity of both

the usual laundry since there is danger of crushing the fastener, but have been laundered without being put through the

FIG. 3. Final position, without patient, viewed from side of operative field.

operator and assistants is far greater than when using the stiff metal hoop. The actual time used in applying the drape is only a few seconds after familiarity is established.

The talon fastener has been used only during the past four months prior to which time a series of small clips or safety pins were used. These were entirely satisfactory but were not as convenient as the present modification. The metal fasteners as now used have stood up under use in a surprising manner, some of them having been used fifty times without showing any defect. They have not been sent through

FIG. 4. Side view of complete draping.

mangle. The fasteners are not expensive and with the use we have had of them up to the present, their cost now is only a few cents for each operation. If one does not wish to use the metal fastener the method remains the same by using a series of safety pins from points AB to EF.

This method of draping is reported because it is simple, efficient and increases the ease of operation by giving greater freedom of action, by adding another direction in which traction and other manipulation can be carried out.

PNEUMOCOCCUS PERITONITIS*

ERICH FRICKE, M.D.

NEW YORK

PNEUMOCOCCUS peritonitis is uncommon. For example, at Lenox Hill Hospital, which has 350 beds, there have been but 10 cases within the past five years. This is an average of only 2 cases a year. Inasmuch as practically all patients suffering with pneumococcus peritonitis are referred to a hospital, these figures are a fair indication of the rarity of the disease.

Despite the relative infrequency of this ailment I decided to study it because textbooks and journals have devoted such little space to it. I was further interested in this condition since, at the present time, there is no unanimity of opinion concerning the etiology and the treatment, questions of great importance because of the high mortality in pneumococcus peritonitis.

The history of pneumococcus peritonitis, at least of its chronic form, dates back to before the discovery of the pneumococcus. Since the middle of the 19th century cases of peritonitis which were undoubtedly of pneumococcic origin have been described in the literature, especially in the French journals. However, only since 1890 with the advent of asepsis and the resulting increase of laparotomies, has the pneumococcus been recognized as the causative agent of many of the cases until then termed "cryptogenetic" or "idiopathic" peritonitis. The first comprehensive works on this subject are those of Michaut (1901), von Brunn (1903) and Jenssen (1903). In America, interest in pneumococcus peritonitis was dormant until recently. Only within the past ten years has there been any thorough investigation of this subject.

The disease has a predilection for children up to the age of fourteen. The incidence is greater in girls than in boys. The proportions are variously reported,

but the average is about five to one. Some authorities claim even higher figures. The cases are generally seen in children of the poorer classes. Occasionally adults are stricken with pneumococcus peritonitis, and among these the males and females are about evenly divided. The onset is generally acute. Only rarely is there a prodromal period of one or two days in which the patient complains of general malaise and occasionally of cough or a gastrointestinal upset. Pneumococcus peritonitis in conjunction with a lobar pneumonia is reported in only single instances. Much more frequently there are references to a preceding bronchitis or tonsillitis.

As already stated, the onset is usually acute. The disease starts suddenly with nausea, vomiting and severe abdominal pains. The temperature is high. Constipation is the exception, diarrhea the rule. The latter can almost be considered pathognomonic. There is frequency of urination. The general condition is fairly good at the onset. This is the more remarkable since the mortality is very high in this stage. It is most probably explained by the absence of the "facies abdominalis" which one is accustomed to see in severe cases of peritonitis. Instead of this, cyanosis of the face, especially of the lips, is noted and is frequently associated with a herpes labialis. The pulse is good at least during the early stages. This is also noteworthy, as we usually expect a poor pulse in generalized peritonitis. An early diagnosis of generalized peritonitis is obvious. There is tenderness over the entire abdomen, with rigidity of the muscles. This latter is not as marked, however, as in a case of perforated appendicitis. The abdomen is comparatively softer, less resistant and feels somewhat "doughy." The blood count is high, frequently show-

* From the Surgical Service of Dr. Carl Eggers of the Lenox Hill Hospital. Submitted for publication September 25, 1929.

ing a leucocytosis of 30,000, with a polymorphocytosis of 80-90 per cent. A positive pneumococcus blood culture is common according to the reports. Pneumococci can also be recovered from the spinal fluid.

This is the typical picture as it is most commonly seen in children. There are, however, other rare forms, in which the course is more chronic. Still others develop a bronchitis or a pneumonia in the early days of the illness.

The acute stage either ends in death in a few days, usually three to four, or, in unfortunately but a few of the cases, enters the chronic stage. The temperature falls. The patient gives the impression of having overcome the systemic infection. Vomiting and diarrhea cease. Abdominal tenderness is less. After about ten days, sometimes sooner, sometimes later, the temperature again begins to rise. The abdominal circumference increases and palpation discloses fluctuation with the formation of an exudate which later develops into an abscess sometimes reaching considerable size. This abscess either leads to death with the picture of a marked cachexia, or it breaks through the abdominal wall, most commonly at the umbilicus. This umbilical abscess and perforation were described as a typical clinical entity long before the advent of asepsis. And even with drainage, such an abscess can occasionally form metastatic foci elsewhere, for example in the bones or joints, from which foci pneumococci can be recovered.

I will now summarize the 10 cases of pneumococcus peritonitis that have occurred within the past five years at Lenox Hill Hospital. There were 8 children and 2 adults. Of the children 7 were girls and 1 was a boy. It was interesting to note that 6 of the children gave histories of having had whooping cough at some time before their present illnesses. Similar observations have been reported by others. With the exception of one case none of the 8 children had a cough before the onset of the abdominal pain. The pain started

suddenly in all 8 cases. In one case there had been a similar mild attack one month before. Examination of the lungs revealed signs suggestive of bronchopneumonia in 5 of the cases on the day of admission, which would mean about one or two days after the actual onset of the illness. The examination of the other 3 cases showed no lung changes. Seven of these cases were operated upon on the day of admission, and an abdominal puncture was done in the case of the other child on the day following admission. In all the cases operated upon, the appendix was removed, and in one case the right tube as well. Pneumococci were found in the abdominal pus of all the cases, and all four types were represented in the series. In only one case was a blood culture and a spinal fluid culture done, both of which showed pneumococci. Six of the 8 cases died, among them being the case in which only an abdominal puncture had been done, and also one case which had received pneumococcus serum. Both of the cases that recovered showed a tendency towards chronicity from the start. One of these cases was the boy, and the other was one which later developed metastatic foci in which pneumococci were demonstrated.

Both of the adults were women. The first patient was thirty-three years old. She was admitted with a beginning peritonitis following abortion. The blood culture showed pneumococci. This patient was not operated upon, but was treated with pneumococcus serum. She survived. The other case was a private patient of Dr. Carl Eggers. The patient, twenty-three years old, was suddenly seized with abdominal pain thirty-six hours before admission to the hospital. The lungs showed no changes. The abdomen showed the picture of generalized peritonitis with tenderness more marked on the right than on the left. A diagnosis of a ruptured appendix was made. At operation, free pus coming from a bilateral pyosalpinx was found in the peritoneal cavity. Both tubes and the appendix were removed. The

pathological report showed that both tubes were open at their fimbriated ends. Pneumococci were demonstrated in the pus from the right tube. The pus from the left tube and from the peritoneal cavity were sterile.

The diagnosis of pneumococcus peritonitis is of practical importance, because as we will see later there is no unanimity of opinion as to whether operation is indicated or contraindicated. Certainly, in many of the cases, especially in adults, it is impossible to differentiate between generalized peritonitis and pneumococcus peritonitis. However, in children, particularly in girls, the symptomatology is sufficiently clear-cut to make a diagnosis of pneumococcus peritonitis if one but keeps this condition in mind. The clinching of the diagnosis is, of course, only possible through the isolation of pneumococci from the blood stream or from fluid obtained by abdominal puncture. And this proof must be obtained as quickly as possible, for delay in making the differential diagnosis, for example of a perforated appendix in which every hour counts, may lead to the death of the patient. Other conditions which must be differentiated are gonorrheal peritonitis and abdominal typhoid. Neither of these, however, has such an acute onset as to necessitate immediate operation. Streptococcus peritonitis must also be considered, but it is even more rare than pneumococcus peritonitis. In fact the opinion has been voiced not infrequently that cases of streptococcus peritonitis described in the literature really were of pneumococcal origin, since it is at times very difficult to differentiate streptococci and pneumococci culturally. In the chronic cases, there may be difficulty in differentiating it from an appendiceal abscess and from tuberculous peritonitis. However, a mistaken diagnosis is not of such importance in those cases. An abscess, whether it be an appendiceal or a pneumococcus abscess, must be opened. And in tuberculous

peritonitis, a laparotomy is good therapy anyway.

ETIOLOGY

There are many divergent opinions as to the etiology. Pneumococcus peritonitis is generally regarded as either primary or secondary. This differentiation does not seem very rational to me, for in calling a case primary, one merely admits that one does not know in which way the peritoneum was infected. It is therefore but a term of convenience.

There are three possible ways for bacteria to enter the peritoneum. The first is via the intestines, the second via the genital apparatus, and the third via the blood or lymph streams.

The intestines have been considered as the portal of entry in this infection, because sputum is swallowed, especially by children, and in this way the organisms might wander through the enteric walls. Jenssen in some interesting experiments demonstrated pneumococci in the intestinal wall of mice that had been fed cultures of pneumococci. However, he did not produce a peritonitis. Wolfsohn repeated this experiment. Several of his animals developed a sepsis, but not a peritonitis. On the other hand, other researches failed to produce any pathological changes in the animals fed on pneumococci. On the basis of this work, it is fair to assume that a pneumococcus peritonitis cannot result from infection from the gastrointestinal tract.

Since the incidence of this illness is greater in girls, our attention is focused on the female genital organs as a possible port of entry. Is it not likely that the organisms may travel up the Fallopian tubes as they do in gonorrheal peritonitis? This view is supported by the observation that in many cases the infection commences in the pelvis minor. Furthermore, cases have been reported in which the peritonitis followed either abortion or childbirth. The 2 adult cases described also seemed to indicate an ascending type of

infection. Koennecke is of the opinion that the pneumococci swallowed by children with their sputum reach the genitals by way of the anus. Actually, pneumococci are frequently found on vaginal smear.

Whether or not these findings are positive proof is doubtful, for pneumococci are also found in the vaginal smears taken from perfectly healthy women. The organisms in these instances are not virulent however, and exist in symbiosis with other forms of bacteria. Besides pneumococci can be cultured from the urine of women suffering with pneumococcus peritonitis. It is therefore not at all certain that in primary pneumococcus peritonitis, vaginitis precedes the peritonitis. Furthermore, since pneumococcus peritonitis occurs in women who have had a complete extirpation of their genital organs and also in pregnant women, and since it occurs with the same clinical picture in men, the portal of entry must of necessity be other than through the female genital organs.

We have seen that pneumococcus peritonitis begins not only as a general toxemia, but that in many cases we have also been able to culture the organism from the blood stream. Does not, therefore, the thought of a hematogenous infection with the primary portal of entry in the upper respiratory passages or tonsils seem much more plausible? This is comparable to many instances of generalized sepsis with metastatic foci. Pneumococcus peritonitis can also be considered a metastatic manifestation of a general pneumococcus septiemia. The report of Schmidt in 1911 lends further support to this contention. He reported a large series of cases of pneumococcus peritonitis following an epidemic of an infection similar to grippe. It is well known that a peritonitis and a pneumonia are frequently confused in children. Is it not reasonable to assume that these are cases of a bacteremia with a transient irritation of the peritoneum? The question has also been raised as to whether the infection might not also be carried

by the lymphatics. However, that hardly seems possible, for the direction of lymph flow is from the abdomen to the thorax and not reversed.

Of course, in accepting the idea of a hematogenous portal of entry, one must consider the experiments of Jensen in which he recovered pneumococci from the blood stream of animals within a few minutes after injecting the organisms into their peritoneal cavities. However, this theory does not explain why girls are so much more commonly stricken than boys. An attempt has been made to explain this on a basis of lessened resistance on the part of the female peritoneum to pneumococci in a similar way as we explain the hematogenous infection of the peritoneum on a basis of lessened resistance. Vollhard and others have strengthened this view with cases of nephroses with ascites in which a pneumococcus peritonitis developed as a result of an already damaged peritoneum.

To summarize briefly the above, it is my impression that the large majority of the cases, especially those occurring in children, are based on hematogenous origin, and that only occasional cases, usually in adult women, are based on ascending infection of the female genital tract.

PATHOLOGICAL AND ANATOMICAL FINDINGS

Early in the disease there are inflamed distended loops of gut with a cloudy exudate which soon becomes mucopurulent and which is odorless. This pus has the tendency to form fibrinous strands, a sort of pseudomembrane just as we are accustomed to see in pneumococcus empyemas. These membranes soon tend to wall off the purulent exudate. The resulting abscesses are often immense and often fill the entire abdomen, pushing the matted loops of intestines backward toward the spinal column.

MORTALITY

The mortality in this disease is unusually high. Those cases that are operated upon

in their early stages show a mortality of 80 to 90 per cent according to the figures of Jenssen, von Brunn, Rohr and Budde. Koennecke's figures are somewhat more reassuring, showing a mortality of about 50 per cent in a series of 27 cases. Of course, the differentiation of the two forms of peritonitis varies, and the transition between the diffuse and the encapsulated forms is gradual so that this may explain the discrepancy in the mortality figures of the different men. The prognosis in the chronic form is naturally better. The mortality in operated cases of this type is only about 10 per cent. There are unfortunately no statistics for unoperated cases. Our interest, therefore, lies chiefly in the diffuse forms that either were not operated upon at all, or were operated upon later in the stage of encapsulation. In the past few years there have been a large series of cases reported in which expectant treatment was used with good results.

TREATMENT

There can be no question concerning the treatment in those cases in which an abscess has formed. An abscess must be incised and drained. In a transitional case, that is, in a case where the early diffuse stage has been survived, but in which the encapsulation and abscess formation has not been complete, it is better to wait so as not to destroy any adhesions which have already been formed. Budde has shown that the mortality during this period, which he considers as being from the fourth to the tenth day, is considerably less than in the early stages.

The only question about which there can be any doubt is what to do in the early stages. As already stated, the mortality in the cases operated upon during the first days is 90 per cent. Surely the mortality of the non-operated cases cannot be higher. We may, at least, assume that some of the cases described in the literature as operated upon during the transitional and chronic stages must have passed through an acute stage. Because of the

high mortality of operation in early cases, the consensus of opinion in the past few years has swung towards waiting in these cases. American surgeons were the first to express this opinion (Kahn, Meredith, Syms, Lilienthal, Beavan, Marshall), but there are now also in Germany a large number of surgeons (Strauss, Remijnse, Budde, Salzer) who condemn early operation. They all point out that one form of peritonitis, namely gonorrheal peritonitis, has been successfully treated for a long time by conservative waiting. This form of peritonitis, however, is not a generalized one. It is their contention that early operation in pneumococcus peritonitis is contraindicated because in its early stages it is a systemic generalized infection and operative interference can do more harm than good. It is better to let the body fight off the invading organisms unmolested, and to aid and conserve this resistance with conservative measures. Most of the surgeons who favor early operation do so because of their difficulty in diagnosing this condition. And that, of course, is the determining factor. It is not always possible to make a positive diagnosis of pneumococcus peritonitis, because due to the urgency of the case, one cannot usually wait for a positive culture. One has to content oneself with a smear of the pus obtained through abdominal puncture, and attempt to find pneumococci in this smear. Neuhof and Cohen have published a series of 100 peritonitis cases in which they found the exciting organism through abdominal puncture without any instance of the dreaded complication of puncturing the intestines. If one should decide on an operation, the purpose should be merely to drain the peritoneum. The question of irrigating the abdomen has not been settled. Irrigations with saline, ether, diluted bile, optochin and rivanol have been tried, but without any noteworthy effect. It is questionable whether such irrigations are of value, because adhesions already formed may be destroyed by them. Drainage through the abdominal incision

seems rational, although some surgeons close up without draining. Still others drain through the vagina. This method strikes me as being a particularly good one as it is well known that a colpotomy alone is associated with but little shock to the patient. The sepsis has been treated with optochin, horse serum, autogenous blood and pneumococcus serum injections. The latter serum should be more widely used in early cases and in those caused by the type of pneumococcus against which the serum is specific. We treated 2 cases in such manner. The first, which

had a diffuse peritonitis and was operated upon, died. The second, a chronic peritonitis not operated upon, was cured.

CONCLUSION

We can reduce the appallingly high mortality figures of pneumococcus peritonitis by not operating in the acute diffuse forms, but by treating them expectantly. We can do this because we are in a position today to definitely establish the diagnosis of pneumococcus peritonitis in many of the cases.

AMEBIC DYSENTERY

ITS OCCURRENCE IN ROUTINE SURGICAL PRACTICE*

CHARLES GORDON HEYD, M.D., F.A.C.S., AND ADELE E. SHEPLAR, M.D.

NEW YORK

WITHIN the last two years in the course of a routine surgical practice we have detected 7 cases of amebic dysentery, all diagnosed by sigmoidoscopic examinations and confirmed by positive cytological identification by Dr. Sheplar. It is rather interesting to note that the 7 cases were all in ambulatory patients presenting symptoms of large bowel disturbances and occurred, with two exceptions, in patients who had permanently resided in the neighborhood of New York City. In the preceding eight years only 2 similar cases were identified under similar circumstances. There are perhaps two explanations for this apparent large increase in incidence of amebic dysentery in our own practice: first, an absolute increase in the general population frequency of amebiasis and secondly, as a result of detecting the earlier cases we have naturally been on the lookout for other cases. It is a regular and routine procedure to do a sigmoidoscopic examination upon all patients with any symptoms of bowel trouble. The symptomatology and the history of patients with amebic dysentery is, as a rule, distinctive and the sigmoidoscopic appearance of the lower bowel quite characteristic. The case histories are herewith given briefly and chronologically:

CASE I. C. M., female, married, aged thirty-eight, Saleslady. Complaint: diarrhea, cramps, passing of blood by rectum, loss of weight, anemia. Always resided in New York but made frequent trips to Illinois and Iowa. Duration of symptoms, six months. Diagnosis: subacute amebic dysentery.

CASE II. E. C., male, married, aged forty-six, Journalist. Complaint: general abdominal cramps, lack of strength, occasional blood in

stools, loss of weight. Always resided in California until recently. Duration of symptoms, eighteen months. Diagnosis: chronic amebic dysentery.

CASE III. R. C., male, aged fifteen, school-boy. Complaint: abdominal pain, diarrhea, with blood and mucus, rapid loss of weight and strength. Resided in New York until recently when patient went to a school in Tennessee. Duration of symptoms, four weeks. Diagnosis, acute amebic dysentery.

CASE IV. L. J., male, aged twenty-four, single, life guard. Complaint: passing of blood, diarrhea, indigestion, abdominal pain and gas. Always resided on Long Island; never been outside of New York State. Duration of symptoms, three months. Diagnosis, subacute amebic dysentery.

CASE V. C. D., male, aged forty-two, married, credit clerk. Complaint: diarrhea and passing of blood. Resides in New Jersey, commutes to New York. Duration of symptoms, two weeks. Diagnosis, acute amebic dysentery.

CASE VI. M. O., male, aged forty-eight, married, stableman. Complaint: pain, bloody diarrhea. Born in Hungary; resided in New York for the past fourteen years. Duration of symptoms, over one year. Diagnosis, chronic amebic dysentery.

CASE VII. W. H., aged thirty-four, married, dentist. Complaint: intermittent attacks of diarrhea, with bleeding; loss of weight, color and strength. Always resided in New York. Duration of symptoms, eight years. Diagnosis, chronic amebic dysentery.

The 7 patients comprise 1 female and 6 males; the youngest is fifteen years of age, and the oldest forty-eight years of age. Only two had ever been south of the Mason and Dixon line; the female patient, a travelling saleswoman, had made frequent excursions to Illinois and

Iowa. All were native born with one exception, a Hungarian, and the social status of all the patients was, with one exception, slightly above the average. It is reasonable to suppose that at least five of these cases, occurring in Long Island, New Jersey, Pennsylvania and New York City, became infested in their local environment. The youngest patient was probably infected at school in Tennessee. In the Hungarian patient the source is doubtful. All of these patients were ambulatory when they came to my office. A progressive loss of weight, fatigue and some degree of anemia, with attacks of diarrhea, abdominal pain and tenderness in the lower half of the abdomen, associated with the passage of blood and mucus, were present in some degree in all the cases. Even in this small group of cases an acute and chronic symptomatology is readily apparent. Cases III, IV and V were evidently acute manifestations. In these pain was a prominent symptom, with frequent stools at night, with the passage of considerable blood and mucus in the stools.

The other cases were more chronic, with less pain, fewer stools, less blood and mucus, but with a greater anemia, cachexia and loss of weight. A tentative diagnosis of amebic dysentery was made in all of them upon sigmoidoscopic examination. A fresh warm specimen, obtained through the sigmoidoscope by swabbing the ulcerated areas, showed *Ameba histolytica* with ingested erythrocytes in 6 of the 7 cases on the first examination. The one exception showed the encysted form of ameba with cells containing four nuclei. This is a higher percentage of positive findings on the first examination than usually obtains in examining the fresh warm stool.

James, from a very great experience, found that one examination of the fresh warm stool detected a third of the cases; three examinations, one-half to two-thirds, and six examinations 90 per cent of the cases.

In amebic dysentery there are appar-

ently three clinical groups: (1) those actively infested cases consulting a physician for relief during an acute infestation, or an acute exacerbation of a chronic infestation; (2) those latent or mild symptom-producing cases without very manifest trouble but with occasional diarrheic attacks with considerable mucus, rarely blood; (3) those supposedly intact, apparently non-infested symptomless carriers.

Craig from an unusually extensive experience believes that 10 per cent of the entire population are infected and makes the distinction between amebiasis or amebic infection and amebic dysentery. He believes that 50 per cent of the so-called carriers actually have symptoms in the way of general debility, cachexia, anemia and with a variety of arthritis.

Entameba histolytica being a true parasite invades the tissue of the host and theoretically at least there are always lesions in the supposedly symptom-free carrier. Musgrave demonstrated that macroscopic ulcers of the colon may be present without diarrhea and MacNeal showed abundant ameba in the submucous layer of the intestine at the site of the ulcers and within the lumen of the veins and lymphatics. The carriers far outnumber the individuals who have symptoms of the disease. Musser states that 95 per cent of those infested with amebae are carriers. "Symptoms depend upon resistance of the host rather than upon the virulence of the parasite." Dobell and Low classify the general aspect of amebic infection or infestation into the following clinical groups: (1) general amebiasis; (2) amebic diarrhea; (3) amebic dysentery; (4) carriers.

There is only one generally recognized cause of amebic dysentery and that is infection with *Entameba dysenteriae*, or *Entameba histolytica* as it is called in the newer books. However, there are a number of forms of harmless amebae that may be present in the intestinal tract of man, the most common of which are *Entameba coli*, *Endolimax mana*, *Ioda-*

meba bütschlii and *Dientameba fragilis*. These amebae do not seem to be associated with amebic dysentery in man or with its serious complication, liver abscess, according to Stitt.¹ The only importance then attached to these amebae is that they at times have to be differentiated from the pathogenic *Entameba histolytica*. Each of these types of amebae may be present in the stools in two forms: the encysted, which is non-motile, and the vegetative, which is motile. The vegetative form is more easily recognized on account of its change in shape and movements and is the form searched for in the stools of suspected amebic dysentery. The encysted form of the *Entameba histolytica* is present in the stools of the carriers and the convalescent. Cysts are present usually in very small numbers and the various types are differentiated by the number of nuclei, special staining methods being necessary to demonstrate them.

Infection takes place only through ingestion of the cysts, the vegetative state being considered non-infectious. The small number of cysts present in stools accounts for the fact that this type of dysentery exists only in endemic form. If the vegetative form were able to infect, there would be epidemics of amebic dysentery similar to those of bacillary dysentery. Contaminated food is the only source of infection in the temperate zone, the contamination occurring through food handling by a carrier of unclean habits who harbors *entameba histolytica* cysts in the intestines. The vegetative amebae soon undergo disintegration after being passed from the body. Vigorous emetine treatment may prevent the formation of cysts which develop only within the body.

The pathological effect of amebae is usually limited to the large intestine and begins as an acute catarrhal inflammation with the production of mucus; in chronic cases vast quantities of mucus may be formed, so that the stool seems to be composed of nothing but mucus. Amebae

invade the crypts of the mucosa, producing little elevations or nodules with a central plug of yellowish necrotic material. When this sloughs off small ulcers are revealed which may be very minute. The ulcers may coalesce producing large ones with elevated ragged undermined edges. Between the ulcers the mucosa may be thickened and inflamed. Ulcers of all sizes may be present.

Examinations for amebae are made on warm stools passed after taking a saline purgative, preferably magnesium sulphate. Purgatives are considered essential by some workers but are said to increase the difficulty of differentiating between different kinds of amebae. The vegetative forms are readily seen in a thin wet preparation by the low-power objective, because of their highly refractile protoplasm and its bluish tinge. If cells of this type are found they are next examined by a higher magnification. Living amebae show change of form and a flowing-out of finger-like processes and at times slow progressive movement. It is extremely difficult to differentiate the vegetative forms of the various types of amebae and the only real basis upon which the differentiation can be made is the finding of ingested red blood cells within the amebae. Non-pathogenic forms do not engulf red blood cells. Not all stools containing *Entameba histolytica* show this picture. Therefore some other way must be found to distinguish between pathogenic and non-pathogenic types. This can be done by staining film preparations of the stool containing amebae and studying the nucleus. But this is not a simple procedure and the staining in the hands of the inexpert is not always successful, the nucleus being so overstained that its recognition is impossible.

During the past two years we have had submitted for examination material taken directly from ulcers through a proctoscope. Mucus thus obtained was rich in amebae, many of which were filled with red blood cells. In some of these cases examinations were made on material ob-

¹ 1927 Edition.

tained by both methods, that is stools after a saline cathartic, and on mucus obtained from the lower bowel. In several instances the first method yielded vegetative amebae containing no red blood cells while the second method on the same patient showed many blood-engorged amebae. This quick dependable accurate method saves interminable hours of the patient's time spent in the laboratory in production of stools and likewise much of the laboratory worker's time spent in the fruitless search of innumerable preparations for amebae that may not be present, or, if present, not easily recognized as *Entamebae histolytica*. In the busy days of a modern laboratory this shortening of time spent in the diagnosis cannot be too highly appreciated. This proctoscopic method results not only in a saving of time but also in greater precision of diagnosis. The procedure herein described is not new but it is one that is not employed as frequently as it should be.

Our procedure has been to have the patient take a small saline enema about 7 A.M. to clear only the rectum. Without any further preparation the patient presents himself for sigmoidoscopic examination. The introduction of the proctoscope or sigmoidoscope has usually been without pain. It has been inserted anywhere from 10 to 14 inches. At about the sigmoidal-rectal junction one finds an area not unlike a ruptured urticarial bleb. The erosion of the rectal mucosa is without elevation, the edges are irregular, with a bright pink-red base which bleeds readily. Sur-

rounding and lying in this ulcer is a plaque or a number of drops of tenacious mucus. Of striking appearance is the normal mucous membrane between the ulcerated areas. The ulcers are irregularly distributed, and in our experience, have been 1 to 1.5 cm. in diameter. Upon swabbing the ulcer the overlying mucus is detached and when applied to a warm slide active amebae were readily obtained.

CONCLUSIONS

1. A considerable percentage of the population in all the geographical areas of the United States are probably infested with *Ameba histolytica*.

2. The majority so infected are probably relatively free from symptoms, but the supposed symptomless carriers frequently show conditions of impoverished health, or arthritis.

3. When the intestinal infestations: amebic dysentery or amebic diarrhea, produce symptoms, the history and symptomatology is distinctive and clear cut.

4. There are characteristic lesions in the upper rectum and lower sigmoid that can be visualized by proctoscopic examination.

5. The removal of the mucous plug through a proctoscope from an ulcerated area has, in our hands, proved about the most effective way of obtaining the vegetative amebae.

6. Every patient giving a history of frequent stools, mucus and blood, should be examined with the idea of an amebic infestation.

TRAUMATIC INJURIES TO THE PANCREAS*

REPORT OF CASE: RECOVERY

ELIAS L. STERN, M.D.

NEW YORK CITY

TRAUMATIC injuries to the pancreas may be either *subcutaneous*, *penetrating*, or *operative*.

Subcutaneous injuries result from direct or indirect forces applied to the front, side, or back of the trunk. (Fig. 1.)

Penetrating injuries result from bullets, knife wounds, or other penetrating forces.

The pancreas may be injured during the following *operative* procedures: gall-bladder operations, retroduodenal palpation for stones in the common duct, incision for pancreatic calculi, diagnostic biopsy of the pancreas, subtotal gastric resection for ulcer of the duodenum, splenectomy, and nephrectomy of the right kidney.

INCIDENCE

Traumatic pancreatitis, in which the pancreas is the *only* organ originally injured, is an exceptionally rare condition. A survey of the medical literature reveals but a very few cases. This treatise reviews the literature, and gives the account of a most unusual and extremely rare case of injury to the pancreas which recovered following four major operations.

Trauma to the pancreas may cause any of the following pathological conditions: contusion of the pancreas, rupture of the pancreas, acute traumatic hemorrhagic pancreatitis, pancreatic apoplexy due to injury, necrosis or abscess of the pancreas, gangrene of the pancreas, pseudo-cyst of the pancreas, or chronic pancreatitis.

REVIEW OF CASES REPORTED

The first case of injury to the pancreas was recorded in 1827, by Travers.² A drunken woman was thrown to the ground after violent contact with the wheel of a coach. She lived several days. At autopsy, a large intraperitoneal hemorrhage was

found. The liver was ruptured, and the pancreas torn completely across.

Garré³ in 1905 was able to find only 30 recorded cases of injuries to the pancreas, and in only 8 was the pancreas the sole organ injured. Recovery occurred in 3 cases. Garré was the first to cure a case of isolated rupture of the pancreas by suturing.

Von Mikulicz⁴ in 1903 collected the records of 45 cases of pancreatic injury. There were 21 cases of penetrating wounds, and 24 cases of subcutaneous wounds resulting from blunt force. Of the 21 cases from penetrating wounds, 12 were due to gunshot, and 9 to stab wounds. Five of the 12 cases of gunshot wounds were operated upon and 3 recovered; the other 7 were not operated upon and all died. The 3 successful cases were recorded by Otis,⁵ Hahn,⁶ and Ninni.⁷ In 7 of the 9 stab wounds, the pancreas was in part prolapsed. In 2 it was replaced; in 5 it was sutured or ligated and replaced; all these patients recovered. In only 2 of the 9 stab wounds was there intra-abdominal injury of the pancreas, Kuttner⁸ and Hildebrand.⁹

Of the 24 subcutaneous injuries, 13 patients were not operated upon and all died; 11 were operated upon and 7 recovered. The operation consisted of exposure of the pancreas and drainage.

Cowen¹⁰ in 1907 reported a case of subcutaneous injury to the pancreas. The patient was admitted to the hospital with a history of a fall upon the abdomen, four days previously. During these four days he had great pain in the upper abdomen and back, continuous with paroxysmal exacerbations. At operation the lesser sac was distended with large amounts of blood-stained fluid. The patient was left with a sinus discharging 6 to 8 oz.

* Submitted for publication June 24, 1929.

of clear fluid a day, which fluid was most irritating to the skin, and causing a very painful dermatitis. In rupture of the

a rupture of the pancreas, dividing it into two nearly equal portions, was found and there was fat necrosis in the neighbor-

FIG. 1. Cross section showing how forceps applied to front, side and back may injure pancreas.

pancreas, much depends on the condition of the canal of Wirsung. This is sometimes intact although section of the gland appears complete (Leith¹¹). It is sometimes severed, as in this case, and a copious discharge of pancreatic secretion is observed if the patient survives a few days (Schmidt¹²).

In a fatal case recorded by Wilks and Noxon¹³ where the pancreas was so crushed opposite the spinal column as to be divided into two parts, the laceration was unaccompanied by any other abdominal injuries, and at the St. Bartholomew Hospital Museum there is a specimen taken from a patient at whose post mortem examination the pancreas was the only organ found to be injured. In this case the patient had been crushed between two vans and on admission only complained of slight pain in the epigastrium. Twenty-four hours later, he became collapsed, but recovered. Subsequently he vomited, became seriously collapsed, and died *three* days after receipt of the injury. At autopsy,

hood, but no injury of the duodenum, liver, spleen, kidneys, or other abdominal viscera.¹⁴

An injury of the pancreas that caused death on the *fourth* day was produced, in a case reported by Wagstaff,¹⁵ by a fall from a cart on to the left side. At post-mortem examination the other abdominal organs were found to be uninjured.

A case seen by Robson and Cammidge¹⁴ illustrates the serious results that may follow a comparatively *slight* blow over the region of the pancreas. A butler slipped and fell forward against a knifeboard projecting from the end of the table at which he was working. The blow was comparatively slight, and the man did not even fall to the ground. Traumatic pancreatitis followed on what was, at the beginning, probably a mere bruising of the pancreas. This was succeeded by slight bleeding into the gland, which effusion became infected. Acute hemorrhagic pancreatitis resulted. An exploration disclosed a large collection of fluid,

highly blood-stained, in the lesser peritoneal sac, some of which had burst through a small laceration in the omentum into the greater peritoneal sac. There was a general peritonitis present at the operation, and though drainage was freely adopted both from the front and the back, the patient did not survive many hours.

Wounds of the pancreas during *the late war* were extremely serious, and almost invariably fatal. Only one case observed by Moynihan recovered and remained well.¹⁶ The pancreas was examined three years after the injury when an almost complete transverse rupture, healed, was found during an operation for the repair of a ventral hernia.

Hughes and Banks,¹⁷ in their book on "War Surgery," quote only 1 case of recovery after injury to the pancreas.

In another class of injuries due to *crushes and blows*, although the pancreatic lesion is less severe than those just referred to, it is the main result of the injury, and slowly gives rise to symptoms that may be relieved by operation. After the shock of the accident has passed off, the patient may appear to have recovered, but in a longer or shorter time, varying from a few days to several weeks, an abdominal tumor appears, which on being explored, proves to be a distention of the lesser sac with blood-stained fluid. The first case of this kind was recorded by Kulenkampff,¹⁸ and others have been reported by Senn,¹⁹ Kuster,²⁰ and Karewski.²¹ Cases following a blow have been recorded by Ross, Hadra,²² Lloyd,²³ Randall,²⁴ Karewski,²¹ and Robson and Cammidge.¹⁴ Littlewood²⁵ described a case after a kick; W. H. Brown after a crush; and Cathcart and Sheen²⁶ after the patient had been run over.

The case of a man thirty-four years old, caught in a fall of earth, and sustaining a division in the midline of the pancreas, by vertical rupture, is recorded by Heineke.²⁷ The patient made a complete recovery.

Karewski²¹ reports a case of a patient who had been run over after being struck in the abdomen by the shaft of a vehicle. He was able to walk home, but abdominal pain came on shortly afterwards, and an exploratory laparotomy was performed. There was a large quantity of free blood, especially in the region of the gastrocolic ligament, and the head of the pancreas was found to be crushed. The patient lost daily 400 gm. of pure pancreatic juice through the fistula. He lost weight, but the secretion diminished on a fatty anti-diabetic diet and the fistula was eventually closed.

Cases of bullet wounds of the pancreas have been described by Otis,⁵ Sanitas, Bertram, Niemann, Borchard, von Brannmann, Hahn, Ninni, Simmonds, Korte, Mann-Slavsky, Carnell, Jephson, Becker and Kindt. Rarely the pancreas has been the only abdominal organ injured, but in the majority of instances other organs also have been involved in the injury. Penetrating wounds of the pancreas due to stabs or cuts with a knife or bayonet have been reported by Kleburg, Labordene, Caldwell, Dargan, and Kullner.

Cases in which inflammatory changes in the gland have resulted from injury have been recorded by Wandesleben,²⁸ Rolleston,²⁹ and others. In Rolleston's case, an abscess in the head of the pancreas with fat necrosis in the subperitoneal cavity was found at autopsy, eighty days after a blow in the abdomen. The blow had given rise to pain, vomiting, inaction of the bowels, and collapse simulating intestinal obstruction. Hansemann,³⁰ Fitz,³¹ and Prince³² have described cases of necrosis of the pancreas after injury.

In a case described by Mikulicz⁴ a man was caught between two wagons. Eight days after the accident, the patient began to complain of pain and fullness in the epigastrium, vomited, and had dyspnea and a swelling in the upper part of the abdomen. Six days later, at laparotomy, two large cavities containing at least 6 quarts of red fluid were opened.

These cavities were in relation to the pancreas, and a fistula persisted for a while. Finally, four months later at autopsy, a scar 2 to 3 mm. was found at the tail of the pancreas. The patient succumbed to the inflammatory complications.

In the case of Kolaczek, a man was run over by a carriage which passed over his abdomen. The patient suffered immediate epigastric pain which gradually subsided during the following days. *Eight* days after the accident, the patient had severe pain in the epigastrium, with a tendency towards collapse, cold extremities, and a very weak and rapid pulse, and died. At the autopsy, a cavity the size of the head of a full term fetus was found in connection with the pancreas, communicating through an opening about 2 cm. in diameter above the transverse colon, with the general peritoneal cavity. This cavity contained 2 litres of blood-stained fluid. An oblique rupture of the pancreas was found.

These 2 cases of secondary hemorrhages occurred eight days after the accidents. Both had their origin in the substance of the pancreas or its blood supply. Both almost certainly were caused by the digestive action of the pancreatic juice on the walls of the blood vessels. The ferments of the pancreatic juice, principally the trypsin, are greatly responsible for the hemorrhages which frequently accompany rupture of the pancreas. The experience of Wells is very interesting on this subject. He found that it was the action of the trypsin on the walls of the blood vessels which caused secondary hemorrhages occurring about *a week* after the accidents. These are the hemorrhages which make one reserve opinion as to prognosis, when so-called simple accidents are followed by amelioration of symptoms, as in the case of Kolaczek.³³

One hundred forty-five cases were tabulated recently by Schmieden and Sebening,¹ of pancreatic diseases following operation, as follows:

| TYPE OF OPERATION | Cases |
|---|-------|
| After stomach operation | 91 |
| After biliary operation | 38 |
| After splenectomy | 7 |
| After diagnostic excision of the pancreas | 4 |
| After other operations | 5 |
| Total | 145 |

| TYPE OF PANCREATIC DISEASE | Cases |
|--|-------|
| Acute pancreatic necrosis | 58 |
| Purulent pancreatitis | 15 |
| Pancreatic abscess | 10 |
| Pancreatic fistula | 18 |
| Fat necrosis without any pancreatic change | 3 |
| Total | 104 |

Of a total of 62 cases tabulated the following classification is recorded:

Sixty-two cases: 20 cured, 32 died.

| | Cases |
|---|-------|
| Blunt trauma | 31 |
| Gunshot injuries | 26 |
| Stab wounds | 5 |
| Injuries to the pancreas alone (14 cured, 6 died) | 20 |
| Transverse rupture (10 cured, 4 died, 3 died within 24 hrs. after injury; 1 was operated upon and died 16 days after operation) | 14 |
| Gunshot injuries (2 cured, 1 died) | 3 |
| Pressure injuries (2 cured) | 2 |
| Fragmentation (1 died) | 1 |
| Complicated pancreatic injuries (16 cured, 26 died) | 42 |
| Organs injured at the same time | |
| Stomach | 19 |
| Liver | 13 |
| Spleen | 7 |
| Bowel | 8 |
| Kidney | 2 |
| Aorta | 1 |
| Vena cava | 1 |
| Gall bladder | 1 |
| Common duct | 1 |
| Diaphragm | 1 |
| Lung | 1 |

Traumatic pancreatitis occurs probably more often than is generally supposed.³⁴ In the most severe type of case, where there is a direct blow in the direction of the pancreas, there is usually such severe shock to the patient that immediate death results. Usually too, there are accompanying lesions such as ruptured liver, spleen, stomach or intestines. If the patient is operated upon immediately after such an injury, the surgeon's operat-

ing time is of course limited, and of necessity, the gross lesions are taken care of first. For this reason, the region of the pancreas is not thoroughly explored, and many cases of hemorrhage into the pancreas are thus overlooked.¹⁶ At the other extreme there are cases where the trauma has been less severe, and although the pancreas may be injured, the symptoms of epigastric pain or pain in the back completely disappear after a short period of time. It is therefore conceivable that in these conditions the injury is less severe, or the pancreatic tissues more resistant, so that the reparative processes are uninterrupted. Between these two extremes, there are cases varying in intensity of symptoms and complications. Furthermore, the symptoms of pancreatic trauma are in no way characteristic, and an accurate diagnosis before operation is usually impossible.^{35,36}

Fischer³⁸ in 1921, reported 40 cases observed in the literature of injuries to the pancreas, and gives the case reports of 30.

Of 9500 autopsies at the Pathological Institute of Leipzig in seven and one-half years, there was only one rupture of the pancreas.

ETIOLOGY

Subcutaneous injuries may result from blows sustained in fights, falls,¹⁴ kicks, automobile or railroad collisions. It may occur from being run over, crushing between two vehicles, or from falling objects and cave-ins.

Penetrating wounds may be caused by bullets or pieces of shrapnel, knives, stiletos or other pointed penetrating objects. Usually in this type of case other organs are also injured. There is one case on record where the bullet pierced the lesser curvature of the stomach and only injured the pancreas.

The direction of the impinging force is usually from in front, but there are cases on record where the force has come from behind or from the side.

Wounds from sharp instruments and

firearms entering from without, and lacerations, even to complete rupture, from violent outside contusions that do not break the skin, are the traumatic injuries most apt to be sustained.³⁵

The trauma, no matter how mild or severe, if impinging upon the region of the pancreas, may cause symptoms requiring immediate surgical intervention.

On the other hand, the reaction to the injured pancreas may be delayed, so that the inflammation and resulting symptoms may occur as the result of a slight injury at quite a remote date.⁴⁰ There may be absence of pain, and only the presence of a swelling in the epigastrium. This at operation may be found to be a blood tumor connected with the pancreas, a hematoma of, or a fluid effusion into the lesser peritoneal sac. All these symptoms can result from some trauma which happened a few days or weeks previous.

PATHOLOGY

The pathology of injuries to the pancreas varies with the degree of the trauma. The pancreas is so situated that its head and part of the body lie in front of the first and second lumbar vertebrae, the aorta and vena cava, while the rest of the body and tail extend to the left. In front is the stomach and intestines, while above is the liver, and to the left the spleen. Below are the kidneys, portal vein and the mid-colic artery. With the mildest form of external trauma, there may be no evidence of injury to the skin; the skin may not be bruised, and there may not even be ecchymoses. *But even with an absence of signs of external injury or violence, and notwithstanding what the initial trauma might have been, severe if not fatal damage might have been done.* The structure of the pancreas is such that a very insignificant trauma may result in a serious intraperitoneal hemorrhage.³⁶ Mild and moderate degrees of contusion of the pancreas cause rupture of the small and medium-sized blood vessels, and inflammation occurs as with the extravasation

of blood in any tissue. The pancreas is extremely vascular, being a glandular structure, supplying the digestive ferments trypsin, steapsin and amylopsin. It also supplies the internal secretion from the islands of Langerhans, which control carbohydrate metabolism. In mild degrees of contusion, the extravasation may be very slow, and it may take hours or days before the intraglandular tension ruptures its so-called capsule. Bosanquet and Clogg⁵⁷ state that extensive necrosis of the pancreas itself often results from hemorrhage alone. The nutrition of the gland is interfered with by the pressure of the extravasation within the capsule, and its tissues at the same time are torn up by the escaping blood. With more severe degrees of contusion, the hemorrhage is correspondingly greater, larger vessels are torn, and symptoms of shock and internal hemorrhage therefore manifest themselves within a shorter period of time. There may result extensive and perhaps fatal hemorrhage, or escape of juice with retroperitoneal hemorrhage and inflammation due to *bruising*.³⁹ The pancreas has been broken completely in two from a blow, leaving no external evidence of traumatism, and a person may even have a vehicle wheel pass over him causing his own spine to cut his pancreas in halves without the visible wounding of his skin.

Moquot and Constanti point out that in rupture or injury of the prevertebral portion of the pancreas, the gland alone is injured, as a rule; whereas in rupture of the left half of the gland, other visceral injuries are usually found.

The extravasated blood collects until the limits of the "capsule" are reached, and it is at this time that the tension on the "capsule" causes excruciating pain and shock. With the rupture of the "capsule," or with *initial* ruptures or penetrating wounds of the organ, there is an *immediate* flooding of the free peritoneal cavity, usually the lesser cavity, and retroperitoneal space along the posterior wall of the abdominal cavity. (Fig. 2.)

With *mild* contusion, the injury to the cellular structure of the gland and the rupture of the small capillaries and tubules

FIG. 2. Vertical section in midline.

containing digestive ferments cause an inflammatory reaction, the nature of which is peculiar to this gland. The digestive ferments, it is believed, cause further progressive change in the blood-vessel walls and glandular tissues, resulting in further hemorrhage and extension of the injury.⁴¹ A further source of danger lies in the digestion by the pancreatic juice of the adhesions which the peritoneum produces. The outpouring of lymph is the chief means possessed by the peritoneum of protecting itself from harm; when the thick flakes of lymph are speedily digested by the pancreatic secretion, the avenue for further extension of the septic trouble is at once opened.¹⁶

Mikulicz points out the influence of the pancreatic ferments in cases of injury to the gland, and describes a vicious cycle, as follows:

Small hemorrhages, or disturbances in circulation; from this, necrosis of a small area of the gland; infiltration around this focus of the ferments set free by the destruction of the parenchyma cells; digestive changes in the

surrounding tissue and its vessels, which were until this time unchanged; enlargement of the hemorrhagic focus, partly as a direct result of the erosion of the vessels and partly as the result of the undermining of tissue and the increased pressure from the hematoma; necrosis and destruction of the surrounding parenchyma of the gland; further escape of the ferments, etc. The escape of the ferments of the pancreatic juice from the damaged portion of the gland is responsible for causing the characteristic signs of acute hemorrhagic pancreatitis, fat necrosis, localized peritonitis, and in the later stages, when infection is added, pancreatic abscess.⁴³

It has been shown, both by experimental work and by observations made upon cases submitted to operation, that after the pancreas has been incised, bruised, or torn, its special secretion is poured out from the wound surfaces. The experimental work of Simon Flexner,⁴⁴ Biondi,⁴⁵ and Katz and Winkler⁴⁶ has shown that when the pancreas is so damaged, by injury however produced, its vitality is lowered, and there is an escape of the gland secretion into the parts around. This results in *fat necrosis* as well as active digestion of the tissues with which the juice comes in contact. An acute inflammation of the pancreas, with or without hemorrhage, or subacute or chronic pancreatitis may thus result. The digestion of the pancreatic juice freely poured out results, too, in the provision of an admirable culture material for any organisms that may chance to be present. An infection that the healthy peritoneum could certainly deal with becomes of the utmost virulence when an abundant food supply for the organisms is present. It is almost certain that in all abdominal operations some germs enter the peritoneal cavity. When their numbers are few, the *unharmed* peritoneum can resist them without difficulty, but if the natural powers of resistance of the peritoneum are greatly reduced, they may be competent to produce an acute inflammation with pus formation.¹⁶

Chiare and Pforringer also speak of self-digestive processes in the pancreas.

This disseminated fat necrosis, which Ponfic and others have observed and described, is most frequently seen in connection with hemorrhagic pancreatitis, gangrene and injury of the pancreas, and less often in suppurative inflammation.

The extravasated fluid and blood may collect in the lesser sac, and with the sealing off of the foramen of Winslow, may produce a blood tumor or *psuedo-cyst* of the pancreas. An injury may produce a *true cyst* of the pancreas, either from bruising and tearing of the duct causing stenosis and accumulation of secretion behind the point of injury, or the duct may be compressed and distorted by the scar tissue resulting from the injury to the neighboring gland substance.

There is a peculiar reaction excited when this fluid comes in contact with fat, be it in the omentum, or retroperitoneal spaces.⁶⁰ This reaction of digestive ferments on fat areas causes the so-called disseminated fat necroses. The steapsin of the pancreatic juice causes a digestion or breaking-down of the fat particles into glycerine and fatty acids, which with the calcium salts causes soap formation. Usually bunches of needle-shaped crystals of fatty acids are visible in these areas.⁴³ The combination with the calcium salts often produces in those situations the insoluble white calcium soaps, which add to the whiteness and opacity of the foci. In cases of acute hemorrhagic pancreatitis, they are very wide spread. In animals in which this condition has been produced experimentally, this condition is also found in the subcutaneous fat. These areas of fat necrosis contribute to the irritation and production of peritonitis.

The subsequent changes which might develop, depending upon the severity of the trauma, and the treatment instituted, are mere relative, progressive changes of the process just described. Abscess of the pancreas, either single or multilocular, gangrene and sloughing of the pancreas, either partial or total, are parts of the same disease entity.

Among the later or chronic results occurring from an initial *contusion* of the pancreas, are sclerosis and atrophy of the pancreas, chronic pancreatitis, diabetes, cyst or abscess of the pancreas, peri-pancreatic cyst, disturbances in the digestive functions of the gland, and pancreatic infantilism in adolescents.

With contusions of the pancreas, there is usually some accompanying injury to the neighboring viscera. The liver, spleen, kidney, stomach and intestines may be ruptured, contused or perforated. Injury to the spine and spinal cord are also possible accompaniments. Rupture of the duodenum, jejunum and transverse mesocolon have also been observed. The common bile duct appears always to have escaped, and the great vessels are rarely wounded. Guillemin⁵¹ found a rupture of the coronary artery; Sencert⁵² a division of the splenic artery; and Gulecke⁵³ a wound of both splenic and left renal artery.

The relation of the *solar plexus* to the pancreas and the injury to this plexus by the trauma explains the severe degree of shock and pain which accompanies lesions of the pancreas.

The addition of the element of *infection*, whether introduced from without at the time of the injury, or whether secondary, from direct extension from the gastrointestinal tract, adds a complicatory factor to the already complex condition initiated. By reason of the connection of the pancreatic ducts with the intestines, the injured pancreas is within easy access of an infected mucous membrane.⁴⁸ The easily decomposable substance of the pancreas only needs infection to become acutely dangerous. If infection does not take place, the injury may be repaired as in other organs.¹⁴

Infection of the pancreas is difficult to handle because of the nature of the tissue, and the constant danger of *secondary hemorrhage*. Deaver⁴⁹ in 1912 was doubtful whether hemorrhage ever occurred spontaneously from arterial degeneration. It was

his belief that the pancreatic tissue is so firm and affords such excellent support to its intrinsic vessels, that spontaneous rupture can hardly be expected. In his opinion, the rupture is due to the erosive action of the pancreatic secretion on the vessel walls already weakened by the trauma.⁵⁰ Korte, in an article based upon 44 personal observations reported 6 deaths from sudden massive hemorrhage from the wound, occurring at intervals varying from eleven to thirty-four days after operation. In no other part of the body is there such a marked tendency of an inflammatory process to open the blood vessels, and we can only describe it to the digestive action of the glandular secretion upon the vascular walls already weakened by irritation.

A chronic focus of infection in the pancreatic region, with the usual prolonged course of these cases, invites bacteriemia and septicemia to ensue, with the final hyaline degeneration of organs seen in cases of prolonged illness or infection.

Among the *complications* that might set in, in a case or traumatic injury to the pancreas, are the following:

1. Hemorrhage, which might be immediately fatal in severe cases, or become so if occurring after the lapse of several days or weeks.

2. Peritonitis, which usually is generalized, but if the patient survives becomes multilocalized.

3. Secondary anemia, either due to hemorrhage or prolonged sepsis.

4. Abscess or gangrene of the pancreas.

5. Diabetes.

6. Empyema or subphrenic abscess from extension around an abscess of the pancreas.

7. Psychoses and marked debility from prolonged sepsis.

8. Persistent fistulae and eczema from constant irritation of the pancreatic secretions.

9. Disturbances in intestinal motility and digestion.

Up to 1901 there were only 18 cases of pancreatic abscess from all causes reported.⁴⁷

DIAGNOSIS

The diagnosis of contusion or injury to the pancreas is not always an easy matter. Injury to the pancreas must always be considered in every accident, no matter what the severity of the force might have been, and no matter in what direction the force might have impinged on the body. The diagnosis might be overlooked even when there are characteristic symptoms present, merely because the condition is not thought of. The diagnosis is also apt to be missed in patients who manifest symptoms *a few days or weeks after an accident*.

In a typical case of moderate or severe injury to the pancreas, the most outstanding symptoms are *pain* and *shock*, and the general symptoms of toxic absorption. Moynihan states that "no other catastrophe within the abdomen produces at once such unendurable agony and so profound a collapse." This is due to the *injury to the solar plexus*, which is in the immediate neighborhood of the pancreas, and to the *tension* of the fluid beneath the so-called capsule of the gland. The pain may be in the epigastrium, but usually is in the lumbar part of the back, and the patient is unable to sit up. The pain is absolutely the most severe that the human body can stand, and cannot be relieved by ordinary doses of morphine and atropine. The pain is usually present from the time of the accident, and may persist for hours or days, or until relieved by operation. The pain of hemorrhage into the pancreas is intermittent, being at times very severe and colicky, then diminishing or disappearing, to return later with increased intensity. In other cases of contusion of the pancreas, where the initial injury is of a milder form, the pain may persist for several days, gradually increasing, and finally, with the release of the tension on the capsule, it disappears. This is analagous to the type of empyema of the appendix, which causes severe pain up to the point of the rupture. Sudden relief of the pain is a danger signal, for in several hours, as after a ruptured appendix,

the pain of a peritonitis resulting from the spread of the hemorrhagic fluid of the pancreas sets in. The pain may be in the back, under the left scapula, or between the scapulae. Pain in one of these sites in pancreatic disease is more frequent than pain beneath the right scapula, thus serving to distinguish it from gall-bladder conditions.

The pain in the back has been mistaken for injury to the kidneys and spine, but microscopic examination of the urine and roentgenograms of the spine can rule these conditions out.

Cysts are frequently painless, but in some instances both pain and tenderness are well marked.

Even in abscess of the pancreas, pain is not a constant symptom. It may be absent, as in a case reported by Stibler, but in the majority of cases both pain and tenderness are pronounced.

Hematomata over the epigastrium or over the back should lead one to consider the possibility of pancreatic injury, but even *without* external signs of bruises or contusions, pancreatic injury must be considered.

In contusions of the pancreas, the color of the skin becomes an *ashy gray*, and there is a *cold sweat* upon the forehead. There is a characteristic *cyanosis* around the lips, with an accompanying dyspnea, which if present in any case of abdominal injury should at once suggest the possibility of injury to the pancreas. This was first described by Halstead. There may be patches of slate color distributed irregularly over the surface of the abdomen and limbs. This cyanosis is never found in other forms of acute abdominal conditions. Grey Turner described 2 cases where large patches of discoloration of the skin were attributed to direct action of the pancreatic juice, which in one case reached the umbilicus and in the other, the costo-vertebral angle.

The pulse is rapid in injuries to the pancreas, between 120-130, of small volume, and may even become imperceptible.

In early stages of contusion of the pancreas the *local signs* may be insignificant when compared with the severity of the pain and shock. There is usually only slight tenderness and reflex rigidity in the epigastrium or just to the right or left of the umbilicus.

Tenderness over the spine with reflex spasm of the spinal muscles may suggest fracture of the vertebrae, but this can be ruled out by roentgenographic examination.

Vomiting usually does not occur immediately unless there is peritoneal irritation. The vomiting is then persistent, in spite of the passage of stomach tube or lavage. The vomiting occurs at intervals, and is partially responsible for the rapid exhaustion of the patient. The vomiting consists first of gastric contents, then of bile and mucus in small amounts.

Vomiting occurring in a patient some days after an accident should not be passed off as a gastrointestinal upset without examination, for the vomiting might be premonitory of a very serious condition. Nausea and retching, with hiccough, are more frequent here than in cases where there is intestinal obstruction.

The *temperature* with injuries to the pancreas may rise to 101°–103°F. With abscess formation, where operation is delayed, there are rigors and chills.

Should a pseudo-cyst of the pancreas form, the stomach, duodenum and colon may be pressed upon and seriously displaced. The pressure of a "pancreatic cyst" upwards, onto the under surface of the diaphragm, may cause dyspnea from interference with the function of the heart or lungs, and in cases of inflammatory effusion into the lesser peritoneal sac, there may be pressure on the pericardium through the diaphragm, leading to distressing cardiac symptoms.

Honigsmann gives the following table constructed from the records of 48 published cases to show the interval elapsing between the occurrence of injury and the appearance of a tumor in abdomen:

| Time Elapsed | Cases |
|-------------------|-------|
| 1 week | 2 |
| 2 | 3 |
| 3 | 6 |
| 4 | 4 |
| 5 | 6 |
| 6 | 3 |
| 6 weeks to 2 mos. | 4 |
| After 3 months | 5 |
| 4 | 2 |
| 6 | 3 |
| 1 year | 1 |
| 2 | 2 |
| 3 | 3 |
| 5 | 1 |
| 8 | 1 |

DIFFERENTIAL DIAGNOSIS

One must consider the following conditions in diagnosing a case of injury to the pancreas:

1. *Perforation of the stomach or duodenum.* In these cases there is usually the history of a gastric disorder. The rigidity in perforation is board-like and somewhat generalized. There is no tendency for a patient with a pancreatitis to "double up." Absence of the liver dullness is an important sign of perforation.

2. *Intestinal obstruction* must be thought of because of the persistent vomiting. Visible peristalsis should be looked for, and the occurrence of pain corresponding with the spasm of the intestine noted. Vomiting is projectile in intestinal obstruction, and the ejecta are progressively more and more offensive. Obstipation can occur with pancreatitis and is not, for this reason, a diagnostic sign. Vomiting of fecal matter should at once suggest intestinal obstruction.

3. *Acute appendicitis* is always thought of in acute intra-abdominal conditions, but can usually be ruled out on account of the location, degree and character of the pain.

4. *Pancreatitis*, occurring some time after a trauma, often is mistaken for an attack of *gallstone colic*. However, the pain of colic is relieved by morphine and atropine, and there is usually a history of previous gallstone attacks. Acute hemorrhagic pancreatitis may be accompanied by

jaundice when it results from the impaction of a small stone in the duodenal outlet of the ampulla of Vater. The patient with colic folds his arms across his abdomen, presses against the back of a chair, or edge of a bed, rests a few minutes, and finding no comfort, walks about in agony. A patient with pancreatitis is almost motionless.

Perforation of the stomach or duodenum, intestinal obstruction, gallstone colic, and acute appendicitis must all be thought of in diagnosing an acute abdominal condition in a patient giving a history of injury or accident.

DIAGNOSTIC AIDS

In cases of acute pancreatitis, *abdominal puncture* is of value, but must be resorted to with the utmost care. The finding of thin, watery, bloody fluid should suggest the presence of acute hemorrhagic pancreatitis.

Examination of the *urine* for sugar and the application of the various "Cambridge's tests" may be of value, but the results are not consistent.

Diastase in the urine, present normally only in small amounts, is increased tenfold or more in cases of pancreatic disease.

Lowe's test, which consists of placing 2 to 3 drops of 1:1000 solution of adrenalin on the conjunctiva of one eye, and repeating the dose after waiting a few minutes, might be of value. In cases of pancreatic disease, within fifteen to thirty minutes the pupil of this eye becomes dilated, and remains unchanged, if the disease is not present.

OPERATIVE TREATMENT

As soon as the diagnosis has been entertained, operation should be performed. Delay in operating upon injuries to the pancreas means a positive increase in mortality. The pancreas may be approached from in front, or from behind. The former route is preferable.

To approach from in front, the abdomen is opened by a midline incision from the ensiform cartilage to the umbilicus. When

the peritoneal cavity is opened, the pancreas may be reached in one of three ways:

1. Above the stomach, through the gastrohepatic omentum.

2. Below the stomach, through the gastrocolic omentum.

3. Through the transverse mesocolon.

The route below the stomach is usually chosen. A bloodless spot in the omentum is found, below the greater curvature of the stomach, and a tear made therein and enlarged. The lesser sac is thus opened, and the pancreas exposed. If a cyst is present, it will often bulge forward and below the stomach. With recent injuries to the pancreas, an attempt to *control the hemorrhage* should be made, and to *relieve tension, evacuate septic material and fluid, and establish free drainage*. The pancreas is extremely vascular, and it has numerous blood vessels, some of which are quite large. It is not possible in the majority of cases to arrest the hemorrhage by ligation. The tying of a mass of pancreatic tissue often results in the cutting through of tissue and further bleeding. Very often, the only means of arresting hemorrhage is the use of the deep sutures of thick catgut. Extreme care must be taken to avoid the main duct, the superior mesenteric artery, and the portal vein. Extensive disintegration of the gland should be treated by *gauze tampons and drainage*. If the inflammatory collection of the tensely distended gland is incised by multiple blunt punctures, as is generally advisable, gauze packing and drainage will usually prevent general infection of the peritoneum. Occasionally, a *posterior incision in the left costovertebral angle* will sometimes enable the diseased organ to be freely drained.

Incised wounds are sutured with rather thick catgut on a curved needle, some of the sutures passing deeply, others more superficially. The superficial sutures may be of finer catgut.

If the pancreatic duct be wounded, an attempt should be made to expose and suture the edges of the wound with fine catgut; if this cannot be done, one should

suture the edges of the wound with fine wounded duct. This procedure should not be attempted if the patient's condition does not warrant the prolongation of the operation by this attempt to repair.

Punctured wounds of the pancreas are usually repaired by one or two sutures.

All cases of injury to the pancreas should be drained, preferably by a rubber tube, or cigarette-drain, either by the anterior or posterior route, or both. The use of these drains protects to a certain extent the drainage tracts from the digestive properties of the pancreatic fluids.

The operative treatment of subacute pancreatitis resulting from injuries consists of incision, and drainage of pancreatic sloughs and collections of fluid or pus.

It is advisable, in some cases, to perform a cholecystostomy, to circuit the bile away from, the injured area, and thereby lessen the chances of adding additional factors to the pathology of that region.

AFTER-TREATMENT

This consists primarily of *supportive treatment* to overcome the affects of the shock of the pathological condition, and operation. Stimulation with caffeine, strychnine, digitan, subcutaneous injections of saline, and stimulating enemata containing whiskey should be used. *Constant attention* to the patient for the first seventy-two hours is most imperative, because of the many complications which are possible. Secondary hemorrhage, blockage of drainage tubes, postoperative shock and diabetic coma are some of the conditions that may be expected. An estimation of the blood sugar at intervals is essential after injuries to the pancreas, and insulin should be used when indicated. The blood of the patient should be grouped and a donor kept on hand to be used in case transfusion is necessary. It is only by attending to every symptom religiously that one can hope to save a patient's life after injury to the pancreas.

Should the patient recover from the post-operative shock and survive the

first week, one must be prepared to recognize any localizations of the inflammatory process within the peritoneal cavity. These take the form of intra-abdominal abscesses, which may point either in the lower part of the abdomen, or in the costovertebral angles. Subphrenic abscess with extensions into the pleural cavity have been recorded after injuries to the pancreas. These abscesses should be opened and drained after localizing, using local anesthesia whenever possible.

Pancreatic asthenia, a condition described by Whipple,⁵⁴ sometimes occurs after operation upon the pancreas or biliary tract. The patient is listless, apathetic, unresponsive to those around him; lacks appetite; complains of nausea and may vomit; rapidly becomes emaciated, complains of extreme exhaustion and has no desire to recover. The blood pressure is low. These symptoms appear within two or three days after operation, but are sometimes delayed for many days. They begin insidiously; they often disappear quickly, and the appetite may return all at once. Moynihan has had 3 cases of this kind, and has treated them with 5 per cent glucose solution intravenously followed by insulin.

Speese and Klein⁵⁵ record an interesting case in which insulin was used to safeguard against the defects of carbohydrate metabolism.

Antidiabetic diet should be used, consisting almost entirely of fats and albumen, as advised by Wohlgemuth in 1910. Sodium bicarbonate should be administered to lessen gastric acidity, which excites pancreatic secretion. This should be given with the meals. Pankreon may be given to substitute the pancreatic secretion lost through the fistula. Erepton proved effective in closing a pancreatic fistula in a case of rupture of the pancreas reported by Kroiss in 1911; about 100 gm. were given daily, 20 gm. at a dose, by mouth in sweetened coffee or warm milk; or by rectum in doses of 50 gm. In this case the fistula closed in about

ten days. The skin around the *fistula* which usually develops after operations upon the pancreas, should be protected from the digestive action of the pancreatic secretion, by alternate use of zinc oxide ointment and vaseline.

PROGNOSIS

The prognosis depends upon many factors, the most important being:

1. The severity of the trauma.
2. The direction of the force.
3. The location of the impinged area.
4. The resistance and build of the patient.
5. The severity and rate of the hemorrhage.
6. The time elapsing between the injury and the onset of the symptoms.
7. The time elapsing between the onset of symptoms and the diagnosis and treatment instituted.

The prognosis should be extremely guarded on account of the seriousness of the injury and the many complications which might set in immediately after the operation, or some time after. It is the consensus of opinion that the vast majority of patients with contusions and injuries to the pancreas die.

Disregarding any classification as to *etiology* of inflammations of the pancreas, some idea as to the mortality when treated medically, and by operation may be obtained from the following table:

| Author | Year | No. of Cases | No Operation | Operation | No. of Recoveries |
|------------------------|------|--------------|--------------|-----------|-------------------|
| Dreesman.... | 1908 | 36 | 36 | 0 | 4 |
| Ebner..... | 1907 | 20 | 20 | 0 | 2 |
| Lenormant | | 36 | | 36 | 17 |
| and Lecene. | 1906 | 36 | | 36 | 6 |
| Lerich and Arnana.... | 1909 | 39 | | 39 | 13 |
| Korte..... | 1911 | 118 | | 118 | 73 |
| Linder..... | 1917 | 16 | | 16 | |
| | | 15 | | 15 | |
| Bloodgood.... | 1919 | 11 | | 11 | 8 |
| Deaver and Ashhurst... | 1921 | 193 | 32 | | 8 |
| | | | | 161 | 67 |

Schmieden and Sebening, in a study of 150 cases of pancreatitis *due to all causes*, give the following table concerning the operatively determined degree of pancreatic pathology and the cures for the various stages; the figures in the first column giving the percentage of cases of the respective stage which came to operation:

| | Cured, Per Cent | Died, Per Cent |
|---------------------------------------|--------------------|-------------------|
| 9.2 Edema without fat necrosis.... | 76.3 | 23.7 |
| 35.4 Edema with fat necrosis..... | 62.5 | 60.1 |
| 25.1 Hemorrhagic infarcts..... | 36.1 | 56.9 |
| 19.3 Necrosis and areas of softening. | 32.0 | 68.0 |
| 3.4 Sequestration..... | 43.1 | 63.9 |
| 7.6 Abscess formation..... | 39.9 | 37.5 |
| Averages..... | 48.8 | 51.2 |

All who have had experience in treating cases of acute pancreatitis urge immediate operation. Whenever a case is seen before diffuse peritonitis sets in, the surgeon should lose no time in operating to evacuate the toxic fluid. Immediate operation should be done even if the patient is in shock, for *the pathological processes of pancreatitis are progressive*. Where injury to the pancreas is done by penetrating objects, the sooner the hemorrhage is stopped and drainage established the better the chance of recovery. In cases of subcutaneous injuries, operation should be performed as soon as the diagnosis is established.

CASE REPORT

The following is the case report of a patient who was thrown to the ground by an automobile, being hit in the left side and back. The patient suffered severe pain in the back and abdomen for six days, and was about to leave the hospital on the eighth day when she went into severe shock and collapse, and had agonizing pain in the abdomen. Laparotomy revealed a hemorrhagic pancreatitis, with diffuse peritonitis and fat necrosis. The patient recovered after a ten months' stay in the hospital during which time two large intra-abdominal abscesses were opened. Later, a subphrenic abscess developed, which was drained. This case,

being one of the very few which have ever recovered, is described in detail.

Mrs. R. R., aged forty-five years, was hit by an automobile on August 12, 1926. Her past history was negative, the patient having always enjoyed an active and healthy life. About two years prior to the accident, she had a hysterectomy for fibroids, at which time exploration revealed no pathology in the gall bladder or other organs outside of the pelvis. Her appendix was also removed at this time.

The patient's husband and four children are all living and well.

When first seen by me, the patient was in front of her home, having just been transported by the automobile which hit her. She was unable to stand, and had to be carried from the street up three flights on a chair to her apartment. The patient was in moderate degree of shock, complaining of pain in her left hip and lower part of her spine, frontal headache and dizziness. Her pulse was 104, regular and of fair quality. Her skin was cold and clammy, and the face was ashen. Careful examination revealed marked tenderness over the left side of her chest in the posterior axillary line over the seventh and eighth ribs, and marked tenderness in the left hip region and over the lower part of her back. Besides, she had multiple contusions and abrasions of all her extremities. There was also marked tenderness over the lumbar vertebrae with reflex spasm of the spinal muscles, and a diagnosis of possible fracture of the spine was made. The patient was put in shock position with her head lowered, blankets and heat were applied, and whisky and black coffee administered. The patient was moved to the Hospital for Joint Diseases as soon as an ambulance was obtained.

The first day at the hospital, the patient complained of extreme pain in her back and neck, and was unable to raise herself to a sitting position. She also complained of dizziness, and examination by the house doctor was impossible. The following day she felt somewhat better, but the pain in her back and neck persisted. Her pulse was of good volume, but the rate was slightly increased to 84-86. Roentgenograms were taken of her arms, legs and thighs, and lumbar spine, and all were reported negative for fracture. The second day after the accident she felt better, and had entirely reacted from the shock; her pulse

was between 76-82. The third day after the accident, the pain in her back had gone, but it was still tender to touch, and she still complained of pains in her extremities. Two days later she again complained of pain in her back; her pulse was between 74-78.

On the morning of the eighth day following the accident the patient was suddenly taken with severe upper abdominal pain, nausea, and vomiting. Her general condition looked very poor, and she vomited continually all morning. The pain was most excruciating in the epigastrium, radiating to the back, and suggested an attack of severe gallstone colic. Atropine and morphine failed to relieve the pain. Her pulse was very rapid and weak. A consultant who was called made a diagnosis of gallstone colic.

The patient was transferred to the Mt. Sinai Hospital that same day, and was seen by Dr. A. A. Berg that evening. Her blood count was w.b.c. 10,300; polymorphonuclears 88 per cent, lymphocytes 6 per cent, monocytes 6 per cent. A tentative diagnosis of gallstone colic was made, and on account of the excitement and the poor condition of the patient, operation was not performed until the following morning. The blood count that morning was w.b.c. 15,200; polymorphonuclears 85 per cent, lymphocytes 14 per cent, monocytes 1 per cent. Just before the operation, the signs changed somewhat; the pain had been unrelieved by morphine, and the diagnosis was indefinite. Intestinal obstruction and ruptured viscus were also thought of.

At operation a moderate amount of hemorrhagic fluid escaped through the incision, pressing omentum into the wound; this was covered with miliary foci of fat necrosis. Palpation revealed a rather dense gall bladder in which no stones could be palpated. The region of the gastro-pancreatic-colonic area was suffused with blood, and the head of the pancreas was felt to be the size of an adult fist. Puncture of the swelling revealed it to be an hematoma. The body of the pancreas to the left of the median line felt normal. There was an accumulation of hemorrhagic fluid along the gutter of the posterior abdominal wall, from the colon to the pelvis. Numerous foci of fat necrosis were seen all over the fat in the gastrohepatic region and the large omentum.

A drainage tube was passed through the gastrocolonic ligament down to the region of the hematoma in the head of the pancreas,

and another tube put into Morrison's pouch. Cholecystostomy was done, and gauze drains placed down to the subhepatic region around the gall bladder. The abdominal wall was closed in layers. A culture of the gall-bladder bile sent to the laboratory was sterile.

Following the operation the patient was in severe shock. The temperature went to 104.2° , and at times the pulse was so rapid and weak that it could not be counted. At 5 P.M. that day, her hands became cold, clammy and cyanotic, and her pulse imperceptible, and her family was called in because it looked as if she were going to die. However, she reacted to the intensive and persistent stimulation of caffeine, camphor and digifoline by hypodermic injection; whisky, bicarbonate of soda and coffee by rectum; and repeated subcutaneous infusions of normal saline solution under the breasts.

The patient's temperature remained elevated around 102° for *a week*; her pulse was very rapid, between 120 and 160 almost constantly. For four weeks following that, her temperature ran between 100° and 103° , and then a low-grade temperature between 101° and 102° for *three months*. During this time, her wound constantly discharged bile and pancreatic juice, and she showed considerable loss of weight. Her skin was loose, her face drawn, and her limbs were very thin. She also lost a lot of her hair. On October 30, a fairly large piece of stinking necrotic pancreas came out through the wound. This wound continued draining for over *eight months*.

Her hemoglobin on October 22 was 47 per cent which shows what a severe secondary anemia had developed. This gradually improved, as follows: October 29, 53 per cent; November 5, 54 per cent; November 19, 56 per cent; December 4, 56 per cent.

On November 12, her blood count was: w.b.c. 12,300; polymorphonuclears 72 per cent, lymphocytes 25 per cent, monocytes 3 per cent. On December 16: w.b.c. 8400; polymorphonuclears 77 per cent, lymphocytes 21 per cent, monocytes 2 per cent. On December 20, w.b.c. 11,000: polymorphonuclears 78 per cent, lymphocytes 21 per cent, monocytes 1 per cent. On December 31: w.b.c. 5500; polymorphonuclears 71 per cent, lymphocytes 29 per cent.

During the course of the low-grade septic temperature, two intra-abdominal abscesses were localizing, which with careful flaxseed

poulticing came near the surface, the first of which was opened under local anesthesia on January 2, 1927, *four and one-half months* after her first operation. A 2.5 inch left lateral incision with center opposite the umbilicus was made by Dr. Berg. On opening the peritoneum, thick pale greenish pus in a large quantity poured forth. A rubber tube and two gauze drains were inserted into the encapsulated intra-abdominal abscess. A culture of the pus showed *Staphylococcus aureus*. The second abscess localized in the right lower quadrant of the abdomen. This was opened on February 7, 1927, *five and one-half months* after the first operation, by a 2 inch incision under general anesthesia, slightly to the right and below the umbilicus. On opening the peritoneal cavity, a considerable quantity of thick pale greenish pus was evacuated; this pus was also cultured, and found to be *Staphylococcus aureus*. The cavity was well walled off, one rubber tube and one gauze drain were inserted, and the wound left open.

The reaction following the operation on January 2 was quite severe; her temperature rose to 104.2° , and she required stimulation with subcutaneous infusions, digitan, and stimulating enemata of coffee and whisky, but then remained low the next four weeks. Following the opening of the second abscess, the temperature remained low, and her condition gradually improved. These abscesses were unquestionably from the localization of the diffuse peritonitis found at the very first operation in August, 1926. The patient left the hospital on June 6, 1927, having gradually recovered some weight and strength, after *ten months* in the hospital.

In August, 1927, the patient developed signs of subacute intestinal obstruction and pneumonia, and was confined to bed for a week.

In the early part of October, 1927, the patient developed pain in the left upper quadrant and back. Physical examination showed marked dullness at the left base posteriorly, and roentgenographic examination revealed an elevation of the diaphragm on the left side. The patient re-entered Mt. Sinai Hospital. On October 10, blood count showed w.b.c. 13,600; polymorphonuclears 82 per cent, lymphocytes 12 per cent, transitional 4 per cent; eosinophiles 2 per cent. Aspiration at the tenth interspace at the left base revealed thick pus which showed on culture *B. coli*; this pus was also tested for pancreatic ferments,

and amylase was found. On October 11, a *subphrenic abscess* was opened and drained under local anesthesia. An incision was made over the left costal angle between the anterior and posterior axillary lines, and a section of the tenth rib about 2 inches long was removed. The peritoneum was opened. Exploration revealed no large collection of pus as far as could be explored with the finger. The proximity to the splenic vessels prevented any deep exploration and in view of the previous discovery of pus with the aspirating needle, the subphrenic space was drained; three packings were placed under the diaphragm, and two under the liver. After several days, these packings were removed, and the wound discharged pus. The pus continued to drain from this last wound, the opening of which gradually became smaller. On December 3, 1927, her temperature suddenly shot to 104.2°, the patient had a slight chill, and there was a discharge of bile from this wound. The character of this discharge soon became watery, and the patient was finally left with a sinus discharging *pure pancreatic secretion*. On December 30, 1927, the patient left the hospital with a discharging sinus, her general condition having improved considerably. The sinus discharged continually for two months, when the tube was removed, and the sinus allowed to heal. After several days, the patient suffered severe pain in the left upper quadrant, and the sinus had to be reopened to allow a considerable amount of secretion under tension to escape. The sinus continued pouring forth pancreatic secretion, until the middle of March, when the tube was removed, and the sinus again allowed to close. It remained closed for three weeks, and then the patient suddenly developed severe pain in the left upper quadrant. Upon reopening the sinus, the retained secretion was under such tension that it shot out several inches on escaping. The sinus continued to drain until June 23, when it closed, and no symptoms of retention have developed since then.

An interesting point about this case, is that although the pancreas suffered considerable destruction causing a large part of it to slough away, only once was there any sign of pancreatic insufficiency of internal secretion. That was immediately after the first operation in August, 1926. A close control of her sugar metab-

olism was kept by daily examination of her urine, and determination of her blood sugar. On August 21, her blood sugar was 0.128; August 24 0.140; August 27 0.160. Her urine showed 0.55 per cent sugar for the first time on August 26, five days after the operation. On August 27, it showed a faint trace, and on August 29, a slight trace of sugar.

A blood Wassermann test taken May 24, 1927 was negative.

The prognosis from this point is difficult to state. Just how long the sinus will remain closed cannot be stated, nor can one state when the process around the pancreas will heal. One can expect a gradual fibrosis of the remaining portion of pancreas with a final development of a diabetic condition which may prove fatal.

The patient, of course, is always in danger of an intestinal obstruction, from the adhesions within her abdomen. It is also possible that she may get an incarcerated or strangulated hernia in the sac of a ventral hernia which resulted from the first operation.

Her general condition at present is very good, her appetite good, and color excellent. She has three abdominal scars from operations, and one scar in the left lower axilla. She has a postoperative ventral hernia from the first operation, and a possible cyst of the pancreas.

NOTE: As this article goes to press, the patient recently has developed a diabetic condition, with blood sugar of 308 mg. per 100 c.c., and with 4 per cent sugar in her urine. Under careful dieting, her blood sugar and urine have returned to normal.

A slight tenderness and the development of a mass over the region of the tail of the pancreas points, in all probability, to the presence of a pseudo-cyst of the pancreas. This condition, as well as the diabetes, had been anticipated. Notwithstanding her present condition, she is very active and able to do her housework.

I wish to take this opportunity to thank Prof. Luigi Frassi of Milan, Italy, for his personal communications, and Dr. A. A. Berg for his invaluable assistance in this case

CYTOLOGICAL STUDY OF GONORRHEAL PUS*

HEINRICH L. WEHRBEIN, M.D.

BROOKLYN, N. Y.

THE defense mechanism of the human organism against gonococcic infection is still obscure. The facts that animal experiments are not available and that human pathological specimens of uncomplicated gonorrheal infections in all stages are difficult to secure are the two main obstacles to a thorough investigation.

Due to the conspicuousness of the purulent urethral discharge, which consists almost wholly of polymorphonuclear cells, most observers have been led to a viewpoint which considers the polymorphonuclear cell to be the primary defensive tool of the body against the gonococcus. The usually very marked phagocytosis is strongly suggestive, especially in view of the well-known experimental work in staphylococcus and streptococcus infections. The very word phagocyte is already leading or possibly misleading toward a conclusion. However, in spite of the microscopic picture, phagocytosis does not seem to accomplish much beyond the purely mechanical achievement of carrying a certain number of organisms into the urethral lumen where they can be washed away. It even seems that the gonococcus thrives a little better in the presence of pus, and it is quite evident that the polymorphonuclear cell is usually worsted in its symbiosis with the gonococcus. It has been conclusively shown that gonococci which have been devoured grow as well in cultures as free ones, and it also has been shown that the amount of phagocytosis has no bearing on the time of recovery in otherwise uncomplicated cases. It furthermore has been demonstrated that the gonococcus *per se* exerts little positive chemotaxis towards the polymorphonuclear cells, but that the gonococcus endotoxin, which is liberated after the death of the gonococcus, is a

powerful positive chemotactic substance. It seems, therefore, that the polymorphonuclear cell does not occupy such a conspicuous position in the defensive scheme as the clinical evidence suggests.

The other factor which plays a great rôle in theory is immunity in a serological sense. The facts of serological immunity in general are too enticing to be ignored, even if there is no evidence that the body has the power of forming effective antibodies against the gonococcus. This lack of power is really most striking clinically and consequently therapeutic efforts in this direction have been bound to fail and have failed. Antibodies, as demonstrated by the complement fixation test, are merely specific protein reactions; they do not necessarily imply the presence of therapeutically effective antibodies.

But of course the human body is victorious against the gonococcus and therefore must have a defense mechanism of some kind. There are several clinical facts which are clearly indicative of the kind of defense employed. The first is, of course, the fact that the defensive processes are purely local; apparently they occur only where the gonococcus actually lives. The adnexa, the various metastatic foci, and the areas of contact infection (for example the conjunctiva) react to the gonococcus as if they were primary foci and undergo the same rather tedious defensive period as the primary focus.

The second fact lies in the observation that the local defensive mechanism rather quickly disappears with the disappearance of the gonococcus. An anterior urethra will show acute symptoms again if reinfected by gonococci from the prostate; artificial infections of the anterior urethra in chronic gonorrhea invariably produce again an acute urethritis. However, this

* From the Urological Service of Brooklyn Hospital and the Venereal Clinic of the Department of Health, New York City. Read before the Section on Genito-Urinary Surgery, New York Academy of Medicine, April 17, 1929.

second urethritis is usually shortlived, indicating some kind of readiness or preparation. This clinical fact is so evident

FIG. 1.

that most clinicians take a second gonococcus infection much more lightly, provided it occurred within a reasonably short time. On the other hand the first gonococcus infection is usually considered to be a vicious one.

The third suggestive fact is furnished by our therapeutic experiences. It does not seem as if the bactericidal powers of the drug used for urethral injections are so very important; some of the most powerful delay the cure beyond the average time limit without local therapy, and some of the very weakly bactericidal drugs have an undoubtedly beneficial effect, shortening the course of the disease by many days. In other words, it is not the effect of the drug on the gonococcus but its effect on the urethral mucosa which is of primary importance. These considerations, which can be augmented, lead to the assumption of a local apparatus, which is slowly elaborated, which rather quickly disappears, and which is to a certain extent responsive to local pharmacological stimuli. It is evident that the apparatus must be cellular, and since the polymorphonuclear defense has been found to be inefficient, it is indicated that the reticulo-endothelial defense mechanism in gonorrhea be investigated.

The pathological findings in all types of gonococcal infections suggest very strongly that the reticulo-endothelial system plays an important rôle. Plasma cells,

histiocytes, and other large mononuclear cells are everywhere in evidence. Their presence is usually overshadowed by the

FIG. 2.

dense polymorphonuclear cell infiltrations, but the latter is by no means as intense in the tissue as in the lumina of hollow organs and on the mucous surfaces. It is furthermore evident that the polymorphonuclear reaction is mainly due to the amount of gonococcal endotoxin liberated and since the gonococcus grows much more profusely in the urethral lumen than in the submucosa this probably explains the relative distribution of the various cellular elements. In mild and recent gonococcal joint infections the joint fluid contains mononuclear cells rather than polymorphonuclear cells. In histological examinations of recent urethral infections it has been shown that round cell infiltrations occur with great speed, even before the appearance of the purulent urethral discharge. In accumulations of gonorrheal pus it is common to see the zone of limitation to consist almost entirely of plasma cells and histiocytes.

Cytological examinations of gonorrheal pus have been made, but most of them are concerned with the behavior of the polymorphonuclear cells toward the gonococcus or with the numerical index of cells with basophile and eosinophile granulations.¹⁻⁶ Pappenheim⁷ and Neuberger⁸ have both investigated the mononuclear cells of gonorrheal pus. Pappenheim thought that the large mononuclears have a regenerative function and that they appear in particularly large numbers as the disease becomes

chronic. He stated that his average findings showed 10 to 15 per cent of large mononuclears, and 1 to 2 per cent of lymphocytes.

FIG. 3.

Neuberger's comment was that the mononuclear cells have no relation to the stage of the disease or to the prognosis. Aside from this, Wile⁹ has found that the mononuclears in the blood stream are increased in number when a chronic gonococcal infection is present.

In an inquiry of this kind the shortest approach to the problem would be through detailed histological examinations of tissues from uncomplicated infections in all stages. A second route would be through the investigations of tissue reactions towards the various drugs which have been used locally in gonorrhea; and if there should be some reaction mode which distinguishes the effective drugs the knowledge of this reaction should prove to be highly valuable for an understanding of the body's defense mechanism. These approaches are difficult either because of lack of material, or of lack of armament; gonorrheal pus, however, could be easily obtained and while its investigation was not very promising, it could be carried through without much difficulty. It was not to be expected that much could be found in advance of Pappenheim's and Neuberger's findings, but a confirmation of these findings and a stimulation towards research along the lines indicated would have been sufficient. However, these cytological studies brought out a valuable lead which should be the adequate stimulus to more intense and more appropriate investigations.

The technic used in these cell counts was as follows: A small amount of pus

was taken from the anterior urethra with a wire loop and spread thinly on a glass slide. After drying, the smear was fixed

FIG. 4.

by heat and Pappenheim's stain* applied for two to three minutes. After washing and differentiating with alcohol the smear was examined for its percentage of large mononuclear cells and for the presence of gonococci. Usually 500 cells were counted for the determination of the percentage. Stained thusly the polymorphonuclear cells appear green with dark green nuclei. The lymphocytes show a light green nucleus with a bright red cytoplasm and the large mononuclear cells have a very pale nucleus with markedly pink cytoplasm. The epithelial cells have a well-stained green nucleus and usually a light green cytoplasm with the exception of squamous cells, the body of which sometimes shows slightly pink. The gonococci are bright red.

The most prevalent mononuclear cell found in these smears is distinctly larger than a polymorphonuclear cell; its nucleus is round or oval, but sometimes is indented as in the so-called transitional cells of the

* Pappenheim's stain:

Solution 1: Saturated solution of pyronin.

Solution 2: Saturated solution of methylgreen.

Just before staining solutions 1 and 2 are mixed in proportions of 1 to 2 or 1 to 3 or thereabouts according to previous trial. The methylgreens on the market vary considerably. Some stains do not require differentiation with alcohol, but most of them do.

blood stream. The cytoplasm is pink and apparently very fragile; vacuolation and fringing of the margins are common.

a series of smears from each patient, but many times this was impossible either due to a quick cessation of the discharge

FIG. 5. Arrow indicates cessation of treatment.

The cytoplasm usually surrounds the nucleus as a large round mass, but pseudopods and odd deformities are frequently seen. These cells are probably identical with the macrophage of Maximow and are of histiogenic origin. Their phagocytic ability is evident from the detritus of cells frequently found within them; however, gonococci were only rarely seen within. With the usual bloodstains these cells are not very easily identified; some of the cuboidal epithelial cells appear then frequently very much like these wandering cells. Particularly when they appear in plaques or sheets, which is not uncommon, the differentiation by the Pappenheim stain was found to be indispensable. With the latter stain confusion of the large mononuclear cells with epithelial cells is almost out of the question. Other much smaller mononuclear cells are lymphocytes or plasma cells. They are scarce; their cell mass is much more scant and their cytoplasm stains bright red.

An attempt was always made to collect

FIG. 6.

or due to the patient's irregularity of attendance. Altogether 121 patients were examined and 352 smears taken. The average of large mononuclear cells in these smears was 2.3 per cent, the highest being 12.4 per cent and the lowest 0.2

FIG. 7.

per cent. The average of the untreated cases (89) as they came to us was 2.1 per cent; the untreated cases classified as to the duration of their infection showed a slightly declining curve as illustrated in Fig. 1. It seems evident, therefore, that the duration of the disease has little influence on the mononuclear count.

The presence of complications also does not seem to have any bearing, since 37 uncomplicated and untreated cases showed

the lowest 0.2. The curve (Fig. 3) illustrates the rather even and persistent percentages.

FIG. 8. A, acriflavine; O, ol. santali; P, protargol.

an average of 2.5 per cent mononuclears, while 37 cases with complications showed an average of 2.4 per cent. Smears from 6 cases of acute epididymitis gave an average of 2.2 per cent. There is also no difference between first gonorrheal infections and repeated infections. The average of the first is 2.3 per cent, that of the second 2.1 per cent. All the figures given so far were collected from patients who at the time of the examination did not receive any local treatment.

We have no series of cases which were left entirely untreated during the stage of active discharge, but we have a large group of patients who received merely oleum santali by mouth in small doses for many days at a time. Smears collected during this period show remarkably little fluctuation in the mononuclear percentage. The average from these smears is 1.5 per cent; the highest figure is 4.2 and the lowest 0.2. In 68 smears of this kind only one exceeded the percentage of 4. Plotted as curves, slight rises and depressions can be seen; they are not steep and their explanation lies well within the possible limits of error. An illustrative chart (Fig. 2) shows the most marked fluctuation found.

There is also a group of patients treated with injections of $\frac{1}{2}$ per cent silver protein solutions of the protargol type. This group shows findings identical with the group receiving oleum santali. Forty-two smears of this group showed an average of 1.5 per cent mononuclear cells. The highest percentage was 4 and

The next group, however, shows great differences; it concerns 64 smears taken from patients who had been using urethral injections of acriflavine solution (1:4000). Here we have an average percentage of 4.3; 12.4 being the highest and 0.2 the

FIG. 9.

lowest. Not less than 26 smears in this group showed a percentage figure of over 4. Expressed in curves, the influence of the acriflavine appears most marked (Figs. 4 and 5).

Then there is a last group of patients who used injections of necaron in solutions of 1:2000. Necaron is a mixture of sodium silvercyanate and sodium cholate. The average of 24 smears was 3.7 per cent, the highest 10.6 per cent, and the lowest 0.2 per cent. Nine smears of the 24 showed a percentage higher than 4. The curves too (Figs. 6 and 7) show a marked influence of the local treatment on the percentage

of mononuclear cells. Two additional charts (Figs. 8 and 9) illustrating the curves of percentages during mixed treatment are shown for corroboration.

These findings seem to be rather definite and unequivocal. Without local treatment, and during local treatment with protargol, the percentage of mononuclear cells in gonorrheal pus remain low throughout. After local treatment with acriflavine and with necaron a sharp rise in the mononuclear percentage occurs in the majority of cases, the rise being more marked after acriflavine than after necaron. The respective majorities are 22 out of 25 with acriflavine and 9 out of 12 with necaron.

The interpretation of this is difficult, but a suggestion may be made which might prove to be of importance. Acriflavine has been examined as to its local effect on tissue and it has been found that it has a very marked local influence on reticular endothelial proliferation where it is deposited even in highly diluted solutions.¹⁰ This observation has been used to explain its sometimes marked effect on septic infections, since the therapeutic doses are usually so small that the bactericidal effect is negligible. Is it not likely that its activating effect on the reticulo-endothelial elements may also be responsible for these cytological findings? If this is the case and if we admit the rather

striking superiority of acriflavine in acute anterior gonorrhea over most other drugs, then it would be logical to assume that the reticulo-endothelial system is an important factor in the defense of the organism against the gonococcus. Further investigations are being undertaken to clear this point.

If further findings should be affirmative they may lead to an experimental method of evaluating at least partially the drugs which are in use at the present time for the treatment of gonorrhea and others which will be advanced for this purpose. Such findings may also allow an evaluation of the patients specific and individual response towards various drugs which may in turn allow a more individualized and more effective treatment.

CONCLUSIONS

1. Large mononuclear cells are commonly present in gonorrheal pus; their percentages vary between 0.2 and 12.4.
2. The mononuclear percentage is not influenced by the duration of the infection or by the presence of complications.
3. After local treatment of the anterior urethra with acriflavine or necaron solutions sharp rises of the mononuclear percentages occur.
4. Without local treatment and after protargol injections these rises do not occur.

GASTRECTOMY VERSUS GASTROENTEROSTOMY IN GASTRODUODENAL ULCERS*

AUGUST SCHACHNER, M.D., F.A.C.S.

LOUISVILLE, KENTUCKY

ALTHOUGH our knowledge of gastroduodenal ulcers is still far from complete, decided progress has been made. We are still in the dark not only upon many of the refinements, but likewise upon such questions as the causation of gastric and duodenal ulcers, their clinical course, the question as to when they are medical and when they are surgical, and if surgical whether best dealt with along conservative or along radical lines.

There is much to justify the belief that gastroduodenal ulcers are to some extent a by-product of our present-day civilization. A very careful inquiry while traveling in such backward countries as Africa, India, Indo-China, and China has convinced me that such diseases as gastroduodenal ulcers are rareties in comparison with their frequency in the advanced western countries where life is far more strenuous.

The classical experiment of Pawlow is not out of harmony with this thought. We all know of appetites that have been arrested through the influence of unwelcome news, and the effect of wines and a pleasant conversation during a dinner all point to the same end, namely, the influence of the nervous system upon the digestive process. Repetitions of this disturbed process may be but the first step of a functional derangement, which, if continued, may through an altered chemical action result in organic changes such as ulceration and which in a certain percentage of cases may terminate in malignancy. This is hardly an unreasonable hypothesis upon the evolution of the gastroduodenal pathology and one that has possibly been insufficiently emphasized. Once established, the chronicity and prog-

ress of the condition seem largely dependent upon two factors: hypermotility and hyperacidity. The importance of hyperacidity is emphasized by the influence which the location bears upon the existence of ulcer. In the *Magenstrass* of Waldeyer and the pyloric region the factor of hypermotility is presented. On the side of hyperacidity, the almost generally accepted influence upon the origin and clinical progress of the ulcer, especially the duodenal ulcer, there is a fairly well-established belief that the direct influence of hyperacid chyme is, if not the only, at least a very important factor in the production of duodenal ulcers and a still more effective one in the production of the gastro jejunal and jejunal ulcers not uncommonly following gastroenterostomy.

Furthermore, the clinical results almost indisputably prove that those surgical procedures that most specifically deal with hypermotility and hyperacidity are attended with the highest percentage of success.

That there is a medical side to this condition, though somewhat ill defined, cannot be denied, but to wait until perforation, hemorrhage and other complications arise before resorting to surgery is not unlike our past attitude in appendicitis, of waiting for another attack. This is especially true if we remember that ulcer cases get well with any form of medical treatment or even no form of medical or surgical treatment, but unfortunately are not likely to remain well. There is a distinct periodicity in these cases, "an ebb and a flow," which is but a part of our incomplete understanding of the condition.

Out of the haze that still surrounds this, the radical features are gradually becoming more clearly defined and more firmly

* Read at the Centenary Celebration of the Faculty of Medicine, Cairo, and the International Congress of Tropical Medicine and Hygiene, Cairo, Egypt, Dec. 15-22, 1928.

established. This change from the conservative to the radical had its origin in Europe, and is gradually extending throughout the United States. The European surgeons became dissatisfied with their end results with gastroenterostomy, looked further, decided upon gastrectomy and now seem satisfied with their decision. The change to the radical treatment in America has been slower and this slowness many have attributed largely to the powerful moulding influence of the Mayo Clinic, where over 8600 gastroenterostomies have been performed with a claim of 90 per cent cure in gastric and 95 per cent in duodenal ulcers, with but 2 per cent complications of jejunal ulcers. Such a powerful argument from such an authoritative source cannot fail to wield a telling influence. There is no good reason why any one who is able to secure such results with gastroenterostomy should change to the more difficult gastrectomy, since the latter in the best hands can hardly expect to excel this result. But other surgeons have been unable to obtain such results, so they have followed in the footsteps of their European confreres and are satisfied.

Since it is not reasonable to expect a normal human being to prefer the more difficult partial gastrectomy to the much easier gastroenterostomy provided the latter yielded about the same results, it becomes necessary to look elsewhere for the explanation. Since it is easier to do a gastroenterostomy than a partial gastrectomy and since the mortality following partial gastrectomy is much higher, not in the hands of the specially trained few but in the hands of the many not specially trained, the reason that the many at least are preferring gastroenterostomy to gastrectomy seems perfectly obvious. In such surgery, however, the operative procedure is based upon what the operator can supply rather than what the pathology demands.

That gastrectomy in the hands of surgeons not specially trained, though

experienced, has a higher mortality than gastroenterostomy is a well-established fact but in the hands of specially trained surgeons, it has also been established that partial gastrectomy need have no higher mortality than gastroenterostomy and that the end results of partial gastrectomy, such as safeguarding against malignancy, perforation, reactivation, new ulcers, hemorrhage and gastrojejunal ulcers, are so much better than those of gastroenterostomy, that gastrectomy is naturally the accepted operation by those who are able to perform partial gastrectomy without a prohibitive mortality.

The surgery of today is exacting as to results and there are some surgical procedures that demand special training, even from an experienced surgeon, in order to obtain the results to which modern surgery is justly entitled, and partial gastrectomy is an illustration of that fact. The mortality following gastroenterostomy has hardly been fairly balanced against that following gastrectomy. In gastrectomy the danger of malignancy has been obviated through the removal of the diseased area, and for the same reason the danger of perforation, reactivation of the ulcer, new ulcers and hemorrhage are likewise avoided. While jejunal ulcers are not impossible, even after a properly performed gastrectomy in which at least two-thirds of the stomach are removed, they are exceptional instead of being commonplace as they are following gastroenterostomy. In some of the reported cases the operation was no more, or hardly more, than a pylorotomy, but improperly included among the partial gastrectomies. This is misleading inasmuch as the influence upon the acidity is under such procedures scarcely entitled to any consideration and the tendency to jejunal ulcers in some of these cases may be increased for the same reason that they are in the Von Eiselsberg pyloric exclusion.

To come within the pale of partial gastrectomy the radical surgeons insist upon the removal of one-half to two-thirds

of the stomach as the proper amount to secure the desired acid reduction if not anacidity. That gastrojejunal and jejunal ulcers are not impossible in cases where the operation was almost a total gastrectomy emphasizes the generally recognized fact that certain individuals seem to have an ulcer tendency that amounts to an idiosyncrasy. This explains the exceptions but does not invalidate the importance of those measures that are most likely to establish an anacidity as the best although not faultless course to pursue.

Some confusion has arisen and more will follow in the discussion through a careless nomenclature as regards the terms excision and resection, pylorotomy and partial gastrectomy. Reference has also been made to the possibility of the selection of easy cases for partial gastrectomy as an explanation of the low mortality. This same explanation forces itself upon one in considering a large series of gastroenterostomies with a surprisingly high percentage of cures and a surprisingly low percentage of jejunal ulcers. It seems unnecessary to add that no operator of the conservative or radical type is supposed to follow one course to the exclusion of the other.

If the subsequent complications of gastroenterostomy in the hands of trained operators are legitimately counted against those of gastroenterostomy, as they should be, and the subsequent possibilities of partial gastrectomies in the hands of trained operators counted against those of partial gastrectomy, we believe that the mortality following partial gastrectomies will be lower than that following gastroenterostomy, and the end results better, the character of the cases in each being about the same.

According to Lewisohn the mortality following partial gastrectomy in the hands of von Eiselsberg, Haberer, Freidemann and Bohmansenn is about 5 per cent and the same author refers to statistics from leading hospitals in New York City showing a mortality of 7 to 11 per cent

following gastroenterostomies for unperforated ulcers.

In 407 cases, not including those of acute hemorrhage, Finsterer's mortality was 4.4 per cent. In a series of 296 cases operated upon since 1919 he has had a mortality of 2.3 per cent; 207 cases in this series were particularly difficult. More than one-half of the stomach was removed, with a mortality of 3.3 per cent. In the last three and one-half years he has had three deaths in 158 resections, a mortality of 1.8 per cent. He emphasizes that no case died within the first few days of so-called shock of heart failure, and there was not a single death from pneumonia. Forty-three of his patients were between the ages of sixty-six and seventy-six years. This same surgeon, through a careful follow-up of his duodenal cases, claims absolute cures in 94 per cent, only 6 per cent having "slight discomfort due to ventral hernia, cholelithiasis, etc." There were no peptic ulcers.

Stress has been laid upon the removal of a seemingly unnecessary amount of the stomach for a small gastric, or, what seems even more extreme, a small duodenal ulcer. In view of our still imperfect knowledge of the subject, the question arises whether the small duodenal ulcer is the real disease or the result of the disease. If the first holds good, the dictum "moderation in all things" has a foundation; if the last, it has at best a defective foundation and is misleading. If the ulcer is largely dependent upon the hyperacidity, the removal of the ulcer without favorably influencing the provocative condition has certainly a questionable foundation.

The chief claims for gastroenterostomy have been that of drainage and the reduction of the hyperacidity. It is known that with an open pylorus the chyme by preference passes through the pylorus and not the stoma, especially if the stomach is distended. If the pylorus is closed according to the von Eiselsberg technique, the danger of jejunal ulcer, a more serious condition than the original, is considerably

increased, presumably through the shunting of acid chyme directly into the jejunum. As for the reduction of the hyperacidity, this not only fails to occur to the desired degree but with time tends to undergo diminution seriously endangering the merits of this claim; in gastrectomy the tendency is just the reverse, the reduction at the onset is decidedly more pronounced and with time increases.

The influence of hyperacidity is concurred in by all types of surgeons and internists. Further, through partial gastrectomy that portion of the stomach where the motility is greatest is removed. The resection includes not only the ulcer but also the abnormal area commonly attending gastric and duodenal ulcers.

According to Konjetzny and Calima, the pyloric half of the stomach shows evidences in ulcer cases of marked gastritis, a pathological condition favorable for trouble, and that is removed through the partial gastrectomy.

In the gastroenterological department of the Mt. Sinai Hospital between 1915 and 1920, 3 per cent of the gastroenterostomies were followed by anacidity; in the partial gastrectomy cases during the same period, there was an anacidity in 77 per cent. The experience of Lorenz and Shur in 1922 is along the same lines. The frequency of gastrojejunal ulcers in the Mt. Sinai Clinic in gastroenterostomy cases has been 34 per cent. Of these, 18 per cent were confirmed at a second operation, and in 16 per cent the diagnosis was based on clinical symptoms and roentgenographic findings (Lewissohn).

As regard the possibility of jejunal ulcers following a properly performed subtotal gastrectomy, experience based upon partial gastrectomies running into the thousands, representing a number of trained European operators and some Americans, notably at the A. A. Berg clinic at Mt. Sinai Hospital, New York, justifies the belief that their occurrence following partial gastrectomy is the exception that only proves the rule.

In the United States the majority of surgeons still favor gastroenterostomy over partial gastrectomy. In a Western clinic over 8600 gastroenterostomies (combined when necessary with excision) were performed with a claim of 95 per cent satisfactory results, with a mortality of between 1 and 2 per cent in duodenal ulcers, and if combined with cautery or knife excision, 90 per cent satisfactory results with 2 or 3 per cent mortality in gastric ulcers, plus the occurrence of gastrojejunal ulcers in about 2 per cent;¹ results that are practically perfect; but the number of observers who remain unconvinced that such results are possible is steadily increasing.

In the East we have another clinic of note where gastroenterostomy has been discarded in favor of gastrectomy because they were dissatisfied with their results, namely, "a perfect cure in nearly 50 per cent (47) of our cases; to this may be added a small group (19) with fair results." This same clinic was influenced in abandoning gastroenterostomy because of the disastrous gastrojejunal ulcers.

In one series of cases re-examined in this clinic after a duration of four to nine years, 34 per cent suffered from gastrojejunal ulcers of which 18 per cent were re-operated upon and in 16 per cent the diagnosis was based upon clinical symptoms and X-ray findings.

Evidently there is an error somewhere since the claims are conflicting and both cannot be right.

Incomplete as our knowledge is, it is generally conceded that ulcer cases admit of a certain degree of classification: The first is the mild type with periodic activation that apparently or actually gets well under rest and medical treatment. A second is a type in every way more pronounced and with more persistent symptoms that through a gastroenterostomy has the moderate acidity reduced, the emptying of the stomach improved and gets well or is markedly benefited.

¹ *Ann. Surg.* 79: 386, 1924.

There is a third type with a high degree of acidity, a tense nervous state with ulcer symptoms pronounced and frequently resorting to soda or magnesia, hypertonic throughout. This is the type that frequently remains unimproved or is even made worse. It is in this type that we may expect the gastrojejunal ulcers and other complications.

The value of the conclusions in gastro-duodenal surgery is in direct ratio to the accuracy of the follow-up system. It would require an enviable degree of optimism to think of following up 8600 or more gastroenterostomies even if they were all located in the same city, and if spread throughout the land the task of following up this large number is obviously as nearly impossible as it can be, assuming that the questionnaire system, while not without some value, is too imperfect to be seriously considered where exact discriminations are necessary.

The cases that are not cured will fall into three groups: In the first group the unsatisfactory element is such that the patients prefer to bear it rather than to invite what they believe might possibly be worse. They may or may not answer a questionnaire and with or without accuracy. A second group is decidedly dissatisfied and may return to where the first operation was performed, but being disappointed are about as likely to go elsewhere. The third group is the one in which new ulcers form, old ones reactivate or perforate, and lastly, being of the hypertonic type, are the cases more liable to gastrojejunal ulcers with perforations. When the latter complication arises, the patient is too acutely ill to be transported to the hospital where first operated upon, if this happens to be located a hundred or more miles away, and therefore falls into the hands of the local surgeon, who most likely has never been trained to

perform a gastrectomy; but is now called upon to perform a far more serious and difficult operation with the only result that one has a right to expect, and which more than likely is never reported, and therefore the gastroenterostomy statistics upon this feature and to this extent remain serenely untouched.

Since there is so much upon the subject that is still problematic, it is difficult to say what the future will reveal, but in the light of our present knowledge considering the immediate and remote consequences of gastroenterostomy and gastrectomy, the wisdom of the course seems to point to gastrectomy provided the operator has trained himself to the task.

It is difficult to avoid the conclusion that influential bodies like the American College of Surgeons are overlooking an opportunity to influence surgery favorably by urging upon medical schools, and surgeons aspiring to gastroduodenal surgery, a more extended course in surgery upon dogs. Even if a surgeon has a large and successful surgical practice it does not follow that such special training would not be attended with the most wholesome results. The technical side of surgery is an art that can no more be acquired from a piece of paper, however well written, or from extensive observation or even assistance, than plumbing, wood turning or any other art. All of them are immeasurably helpful, but after all, it is actual practice that makes true perfection, and as much of this perfection as possible should be acquired through practice upon lower animals and not human beings. When this is adopted I feel confident that there will be a swing around to gastrectomy as the choice and gastroenterostomy as the alternative and while our results may not be entirely faultless, they will at least be better than they are at present.

PLASTIC ORTHOPEDICS OF THE FOOT AND LOWER EXTREMITY*

A. GOTTLIEB, M.D.

LOS ANGELES, CALIF.

THE disfigurement of the lower extremities may have the most unfortunate psychological effect upon individuals, especially upon women. It may produce an inferiority complex whose ramifications may be both wide and lasting to a surprising degree. Leg and foot defects may seriously interfere with social pleasure as well as with a person's attention to business and profession. In a female individual a neurosis may develop on account of ill-shaped legs or malformed feet. It is such conditions which I wish to discuss, leaving out of consideration the various and manifold orthopedic affections which have resulted secondary to a pathological process in the brain or spinal cord, as for example the acquired talipes of spastic or infantile paralysis; neither will I enter into the description of deformities secondary to local or remote inflammatory processes, such as tuberculosis or pyogenic focal infections leading to arthritides; nor will I dwell even upon the congenital foot deformities, i.e. talipes. This article is devoted to the conservative and operative correction for cosmetic purposes of common conditions which affect the leg from the knee down, conditions which offer difficulties in shoe fitting and interfere with happiness because they insult the patient's esthetic sense.

Enumerating from below upward, the most frequent affections are: (1) hallux valgus; (2) minimus digitus varus; (3) hammer and other malformed toes; (4) excessively long toes; (5) submalleolar lipomata and fat ankles; (6) bow legs; and (7) varicose veins and ulcer.

I. HALLUX VALGUS

A mild form of this defect may respond to conservative treatment by physical

and mechanical measures. Physical modalities to overcome adhesions and contractures; massage, manipulations and muscle training to reestablish function, and padding and night splinting to retain the correction obtained by physical means may overcome many an incipient hallux valgus. The toe may be restored to a position and shape commensurate with the sensible commercial shoe. The foot may assume a presentable appearance. On the other hand, if the toe deviation has become fixed by tissue contracture and the head of the metatarsus has adopted an unsightly shape, only operative procedure can restore the configuration to the forefoot.

The varieties of hallux valgus operations are so numerous that the rehearsing of them would lead us too far. Suffice it to say that the object of all of them is to restore the contour and the function of the foot and with this, to abolish the symptoms and signs of the defect.

The type of operation must be chosen in accordance with each individual case, keeping in mind that the normal anatomical structures and the weight-bearing function of the foot should be disturbed as little as possible. For this reason the Mayo's operation should be limited to cases in which the big toe is enormously long and interferes with wearing of the commercial foot gear. Even in such instances the toe can be shortened by removing a part of the phalanx instead of the metatarsal head. The operation I most frequently perform is as follows:

A 2 in. incision is made on the outer side of the big toe joint. The conjoined tendons of the adductor hallucis group of muscles are carefully exposed and severed from their insertion at the base of the first

* Submitted for publication June 14, 1929.

phalanx. The external sesamoid is not removed, except when extremely displaced, as indicated by the roentgen ray, or when it is abnormally large or eroded. After this, the severed tendon of the adductors and the external head of the flexor brevis hallucis are transplanted into the dorsum of the head of the first metatarsal bone by means of stout catgut or silk thread. Now only is the enlarged metatarsal head exposed and the superfluous bone chiseled away. It may at times become necessary to remove a button from the base of the phalanx in order to straighten the toe. The toe position is now corrected and held in position by means of a plaster shoe or splint. Weight-bearing is allowed in about eight to ten days.

While this operation is my choice, I deviate from it whenever circumstances warrant, as indicated by the findings in the operative field and by the roentgen ray. All cases should be roentgenographed preoperatively to give a clue to the mode of operation and postoperatively to present the results. After-treatment with physical modalities and the wearing of a foot support and properly fitted shoes should always be practiced. Many well-performed operations present bad results because painstaking after-treatment has not been carried out.

2. MINIMUS DIGITUS VARUS

The deviation of the little toe towards the midline of the foot and the prominent head of the fifth metatarsal can be overcome by methods similar to those outlined for hallux valgus.

The conservative treatment is practically the same only that the strapping and splinting of the little toe differ from those of the big toe. These measures may suffice if the condition has not advanced too far: if the toe has not become permanently fixed in the malformed position by contractures of the joint capsule and the tendon of the dorsal flexor.

For the operative correction of the

minimus digitus varus two methods are advocated. One is as follows: A part of the head of the metatarsal and, if need be, a portion of the third phalanx are chiseled off, thus removing the offending prominence which makes the forefoot too wide. Capsulotomy and tenotomy may have to be added if the toe is dorsally flexed and contracted.

The other operation is to perform an osteotomy of the fifth metatarsal shaft and to shift the distal portion to the midline of the foot. In this corrected position the metatarsal unites. I have obtained the best results by the former method which is simple and effective.

3. HAMMER TOE AND OTHER MALFORMED TOES

The amputation of deformed toes should be condemned because a predisposition for much functional disturbance and for subsequent malformation is thus created. An exception may be allowed with the little toe when it is very much deviated towards the midline and when it markedly overrides or underrides the neighbor. Only after failure of conservative and operative procedures should advice be given to amputate, even in the case of a little toe. While the loss of the last toe may but rarely cause trouble, the foot has lost its normal, its natural appearance.

Toes should be restored to comparative normalcy in shape and position. The most common defect is the hammer toe. If many toes are thus deformed we have the claw foot to deal with.

Conservative measures, i.e. physiotherapy, including manual and mechanical stretching and adequate supporting, may sometimes be sufficient to give satisfactory correction of a mild hammer toe. But in more extensive deformity it is usually necessary to tenotomize or to lengthen the extensor longus tendons, to tenotomize the toe flexors and at times even to perform a capsulotomy of the metatarso-phalangeal articulations.

Tenotomy releases the tendon contrac-

tures; capsulotomy relieves the capsular shortening of the joint beyond the head of the metatarsal. There is no doubt that this simple section of tendon and capsule may suffice, if followed by the mechanical and physical measures already mentioned.

Whatever treatment is instituted it is not wise to apply much force in the manipulative correction of the toes. This may lead to swelling from rough handling, from tearing and stretching of the capsule and tendon. Not only may it result in a failure to straighten the toe, but may greatly add to the suffering of the patient and to an increase of the defect.

In cases of long standing which offer excessive resistance to manual manipulation, even after tenotomy and capsulotomy, a bone operation should be resorted to.

This consists in a subperiosteal removal of sufficient bone to allow over-correction of the toe without any force. A wedge of bone is resected from the phalangeal articulation and the bone ends allowed to unite. This is the most satisfactory procedure to abolish permanently the flexion contracture of the phalangeal hammer.

4. EXCESSIVE LONG TOES

The difficulty of fitting a commercial shoe when the foot is too long on account of a protruding toe is obvious. The amputation of a terminal phalanx, as advised at times, should not be performed, it being only an additional disfigurement. A square piece of bone should be resected from the middle phalanx in the lesser toes, or from the second phalanx in the big toe. A very satisfactory and cosmetic result ensues, especially when a flap of fascia is interposed into the joint to prevent ankylosis.

5. SUBMALLEOLAR LIPOMA AND FAT ANKLES

Fat lumps anterior to the external malleoli are a rather common occurrence in women. While they do not give any

subjective symptoms, they always render the ankle ill-shapen in appearance.

I have attempted to reduce these fat masses by conservative means, but never succeeded. No massage, nor any form of physiotherapy including the advocated negative galvanism, has lead to a permanent reduction of the size of these masses of adipose tissue.

Enucleation through an open incision is the only procedure which has abolished this unsightly tumor. The removal is simple and the final result is satisfactory.

Besides the submalleolar lipomata, an ankle may be large in virtue of circumferential fatness of the lower leg. By conservative means I was not able to gain any appreciable and lasting reduction of the leg contour. As conservative therapy I used the well-known *Zinkleimverband*. The technique of its use I will describe under the discussion of varicose veins. This cast or bandage may be of temporary usefulness if continued for a long time. Unfortunately the effect of this treatment is only temporary; the condition usually returns a short time after interruption of casting.

The operative removal of fat to gain a better shaped ankle in this circumferential leg fatness is still in the experimental stage. I have personal experience in only 2 cases. The site for the operation is in the midline over the tendon Achilles. The incision is about 6 to 8 in. long through the skin and subcutaneous tissues, thus exposing the layer of fat. The latter is removed by a long strip or by curettement on each side of the tendon, leaving sufficient fat on the skin so that it may present an even outline after healing. After the stitching, which should in these cases be subcutaneous, a tight compression bandage is applied and left on for at least ten days. The last word in this plastic operation of the lower part of the leg has not been spoken yet. To my knowledge, nothing has been published to date on this subject. Although I cannot with certainty advocate operative procedures for a successful

restoration of the leg outline, I think it is worth trying, since no bad effects or dangerous results can ensue.

6. BOW LEGS

This type of deformity is not uncommon in the adult, although extreme bowing is relatively infrequent. After massage, manipulations and the wearing of all kinds of commercial supports have been in vain, the woman will consult the orthopedist with the request to have the legs straightened. The psychic burden is so great in this malformation that even operation is requested. To gain a good cosmetic effect it is essential to have roentgenograms taken of both legs for the sake of comparison and to determine the type of operation to be performed. Only cases with mild knock knees give promising results. Whenever the knock knees are markedly developed, straightening of the legs will result in a worse appearance of the entire lower extremity than before the operation.

The operation is comparatively simple. It consists of an osteotomy or a wedge-shaped resection of a piece of the tibia and a division of the fibula, on a little higher level than that of the tibia. In three to four weeks the plaster cast, applied immediately after the operation, is changed with the leg in better correction. An attempt at complete correction should never be made at the time of operation; the straightening should be gradual in two or more plaster cast reapplications, each time reducing the bowing of the leg until complete alignment is obtained.

The time necessary for complete recovery is from ten to sixteen weeks. If the bowing is anterior or acutely lateral a wedge-shaped resection of the tibia is indicated, while otherwise a transverse or longitudinal osteotomy will suffice. There are even cases when the fibula may be left intact, the correction being obtained with the severance of the tibia only.

7. VARICOSE VEINS AND THEIR SEQUELAE

This unsightly and troublesome defect

of the leg, which occurs so frequently in women, can be overcome by a method advocated in recent years, namely the obliterative treatment of varicosities and the application of Unna's paste for the healing of varicose ulcers and superficial phlebitis, both of which are complications of the distended veins.

The formula for Unna's paste is:

| | | |
|------------|---------------------------------|-------|
| Glycerin | 10 | parts |
| Gelatin | 4 | parts |
| Water | 10 | parts |
| Zinc oxide | 4 | parts |
| Glycerin | 10 | parts |
| Gelatin | 6½ | parts |
| Water | 10 | parts |
| Zinc oxide | 2½ | parts |
| Phenol | ⅓ per cent of the total volume. | |

A modification proposed by Dr. Joseph W. Sooy is:

Ten pounds of this paste is sufficient to make seven boots. While Unna's original paste may serve the purpose, Sooy's modification makes the dressing somewhat antiseptic and inhibits the thriving of organisms under the boot. It increases the porosity of the substance and stimulates healing of the ulcer.

Both pastes are applied in the following manner:

After the paste is prepared, it is placed in a double boiler and is heated to about 100°F. It becomes as viscous as paint. With the aid of a paint brush it is applied directly over the skin of the leg, beginning from the toes and ending below the knee. The ulcer is not protected by a dressing. A simple spiral bandage is wound evenly over the first layer of the paste; then more paste is applied, followed by another muslin bandage. A total of three layers of bandage and four of the paste completes the boot. After cooling, the boot is rubbery hard and forms a pressure bandage which in virtue of its porosity allows the discharge from the ulcer to escape.

The paste boot cannot be regarded as a permanent cure for any condition. It offers only a temporary support, decreasing the venous pressure and improving arterial circulation. It is doubtless a very efficient

measure to reduce edema of the ankle and leg and to favor the healing of the ulcers. The paste dressing can be left in place for as long as twelve weeks without renewing it.

For a permanent cure of the varicose veins the injection method may be considered the most ideal. The treatment is a radical cure. Over the operative methods it has the advantage of being an ambulatory treatment. The pathological principle underlying this method is the formation of a phlebitis of the venous wall. The injected solution acts as an irritant to the intima of the vessel and produces the inflammation, called by Siccard "endo-veinitis." Siccard describes the pathology as a phleboscrosis which actually is a productive adhesive and organizing phlebitis.

The solutions in use at the present time are 15 to 25 per cent sodium chloride, 20 to 40 per cent sodium salicylate, urea and quinine solution and a 60 per cent glucose solution. Other chemicals in solution have been used and given favorable results. The kind of medication has not been decidedly established. Individualization and establishing the proper indication for each solution should be the aim of the men who use this mode of therapy. The technique of the injection also varies somewhat. I proceed in this manner: While the patient is standing I apply a tourniquet below and above the site of the injection. With tincture of iodine I mark the point where I desire to introduce the needle. The patient then lies down and I

introduce the needle. The flow of blood indicates that I have struck the lumen of the vessel. The central bandage is loosened, the leg is raised and the solution introduced. In withdrawing the needle one must be careful not to allow any drop of the solution to infiltrate the subcutaneous tissues for fear of cellulitis, which may easily set up. A sterile gauze sponge is placed over the injected area and strapped on by means of adhesive. An elastic bandage may be applied over the entire leg and left on until the next injection, in about five days.

This method of treatment is most efficacious provided the proper indications are established beforehand and the possible complications forestalled. I do not intend to discuss these here, but desire to add that no recurrences take place. New veins may appear on the leg in a patient with varicose diathesis; in such instances the injections have to be continued into the newly formed varicosities.

It must be admitted that very small varicose veins are not amenable to this injection treatment, hence promises must be guarded against.

CONCLUSIONS

The enumerated defects are only the most common ones in the foot and leg. Their correction is advocated and obtainable for the sole purpose of gaining cosmetic effects and abolishing unsightly and ugly outlines of the lower extremities. The etiology and symptomatology is disregarded, having no bearing on the subject.

ANATOMICAL VARIATIONS IN THE THYROID AS A CAUSE OF RECURRENT GOITER*

J. EARLE ELSE, M.D.

PORTLAND, OREGON

EARLY in the study of goiter a considerable percentage of recurrences were seen following operation. With the improvement of diagnostic ability and operative technique there was a marked decrease. Several years ago in the goiter clinic of the University of Oregon, we began the study of the cause of recurrence. We classified the patients coming in complaining of recurrence into two main groups.

- I. Pseudo recurrences
 - A. Diagnostic errors.
 - B. Symptoms due to permanent lesions
 - C. Insufficient operations
 1. Improper operations
 2. Anatomical variations.
- II. True recurrences
 - A. Without symptoms
 1. Colloid goiter.
 2. Diffuse adenomatous goiter.
 3. Adenoma.
 - B. With symptoms
 1. Toxic hyperplastic goiter (exophthalmic).
 2. Diffuse adenomatous goiter.
 3. Adenoma.

Under diagnostic errors were placed those patients whose symptoms were suggestive of goiter but were caused by other lesions. There had evidently been a goiter which had been removed without influencing the symptoms. With our present-day diagnostic methods and a proper understanding of the value of the basal metabolic rate and sufficient repetition to determine the true rate, these errors should now be minimal. Permanent lesions are the result of neglect, usually on the part of the patient but sometimes on the part of the physician. Permanent lesions in the heart, in the vascular system,

or in the central nervous system, are produced before operation and, although the patient may be cured of goiter, he will still have some of the symptoms.

Under the third group, insufficient operations, are included those patients in whom there was not a sufficient amount of the thyroid removed to produce a cure. Under this group are included as subgroups: (1) improper operations; patients under this group have usually been operated upon by inexperienced operators and not enough gland has been removed to produce a cure; (2) anatomical variations; the operation performed was sufficient for an ordinary gland but the recurrence is due to an anomalous condition.

The patients with true recurrences were divided into those without symptoms and those with symptoms. In the group without symptoms are included patients who have been operated upon and return with a goiter but no symptoms of hyperthyroidism and a normal or subnormal basal metabolic rate. In this group we have recognized: (1) colloid goiter, the most common kind; (2) diffuse adenomatous goiter, and (3) true adenoma. While the latter two groups were not toxic when we saw them, we believe in the course of time they would become toxic, so operation was advised.

Recurrence with Symptoms. Here are included all those patients who gave a history of cure following operation but have returned with a goiter and symptoms of hyperthyroidism. In this group we have found: (1) toxic hyperplastic goiter (exophthalmic); (2) diffuse adenomatous goiter, and (3) adenoma.

Our work upon recurrences began with the study of this latter group. We first studied regeneration of the thyroid in

*Read before The Pacific Coast Surgical Association, Feb. 22, 1929.

rabbits and found that, first, as long as there was a sufficient amount of thyroid gland left to supply the necessary thyroxin

num amount of gland so as to make certain that hyperplasia would take place, first, that an increase in the amount of colloid

FIG. 1.

FIG. 2. Retrotracheal extension. Rubber tube marks position of trachea. There were bilateral retrotracheal extensions which met in midline. Retrotracheal extension made up greater portion of both lobes so that upon exposing thyroid portion presented appeared comparatively small.

FIG. 3. Inferior extension from lower pole.

to the animal, there was no change in the gland as a result of removing a portion of it; second, that when there is a sufficient amount of thyroid left so that stimulated activity of the cells can supply enough thyroxin, there will be an increase in colloid but with no, or very limited, hyperplasia; and third, when there is not enough thyroid gland left to supply the necessary amount of thyroxin, hyperplasia takes place and new gland substance is developed. In some instances this hyperplasia was excessive.

We next undertook the study of the control of regeneration and found that when the thyroid gland was kept saturated with iodine, a greater amount of gland could be removed without hyperplasia than when iodine was withheld. We found, further, that in removing a maxi-

appeared in about two days whether iodine was given or not, second, that hyperplasia appeared in about seven days whether iodine was given or not, and third, that the hyperplasia was usually completed in three to four weeks when iodine was given but that it continued much longer if iodine was not given, and in two instances where iodine was not given the hyperplasia continued until the thyroid had assumed proportions sufficient to be called a goiter. As a result of this work we concluded that true recurrent goiters could be prevented by having the thyroid saturated with iodine at the time of operation and kept saturated for two months after the operation and giving sufficient iodine thereafter to supply that needed for normal function.

In applying this to the patients, we

found while the number of recurrences were markedly reduced there were still some patients who would have recurrences.

cause recurrences as follows: (1) persistent pyramidal lobe, (2) superior accessory thyroids, (3) retrotracheal extensions, (4)

FIG. 4.

FIG. 5.

FIG. 6.

FIG. 4. Inferior extension and extrusion from lower pole. Distal portion has adenomatous mass at its end which was connected to proximal portion by connective tissue only. There was no thyroid tissue connection. Proximal part is an extrusion that was connected to lower pole. It was a true extension of thyroid tissue.

FIG. 5. Extrusion from lower pole connected only by connective tissue.

FIG. 6. Same as Figure 5, showing flattened surface where this mass came in contact with lower pole. There was no thyroid tissue connecting the two.

About this time we saw a patient who had been previously operated upon elsewhere five times. With the ordinary methods of examination, no thyroid gland was palpable, but by standing behind the patient and pressing the fingers of the left hand posterior to the trachea so as to rotate it to the right, a mass could be felt with the thumb and finger of the right hand. Reversing the method of examination, the mass could be forced over to the left side. At operation this was proved to be bilateral retrotracheal extensions that had never been reached. Since then we have been studying every patient that comes to operation for atypical thyroid distribution.

As a result of this study we have classified the atypical conditions seen that may

inferior extensions or extrusions, and (5) lateral extensions or extrusions. Pyramidal lobes appear to be present more frequently than any of the others. The pyramidal lobe is formed by a spreading out of the thyroglossal stalk above the isthmus at the time of the development of the thyroid. It is usually connected by its base to the isthmus but sometimes is independent of the isthmus. It may extend as high as the hyoid bone. At the time of the primary operation the pyramidal lobe may be so thin that it may be overlooked or the surgeon may think it of no consequence. Whenever present, however, it should be removed as it participates in the regenerative process and may form an unsightly mass even though it does not develop into a toxic goiter. Aberrant thyroid masses

originate from the thyroglossal stalk above the hyoid bone and usually lie along the former course of the thyroglossal duct. They are sometimes displaced laterally, but I have seen none of them in my series.

Retrotracheal extensions (Figs. 1 and 2) occur much more frequently than are supposed. This is a congenital condition which, like the pyramidal lobe, occurs so frequently that it can hardly be said to be anomalous. I have seen retrotracheal extensions that will measure as much as $2\frac{1}{2}$ cm. in their anterior posterior diameter. Retrotracheal extensions are frequently bilateral and often meet posterior to the trachea so that the trachea is completely encased in thyroid tissue. At the place of contact the border of each is flattened and when large there is a wide flattened surface. I have never seen them united. The trachea may be compressed. These patients often complain of a tightness in the throat even when no evidence of constriction is seen. In the larger ones the esophagus is pressed against the posterior wall and the patients may complain of dysphagia. At operation every lobe should be everted before removal in order that a retrotracheal extension may not be overlooked. Owing to the close proximity of the recurrent laryngeal nerve, the best method of removing retrotracheal extensions is to evert the gland, place two fingers back of the retrotracheal extension and then, after the capsule of the gland has been opened and the greater portion of the thyroid has been dissected free from the posterior section of the capsule, the retrotracheal extension is inverted into the capsule so that it may be dissected out without injury to that portion of the capsule which covers the nerve. If overlooked, a subsequent operation is fraught with danger due to displacement of the recurrent laryngeal nerve in the healing process. As the scar forms it may be drawn over the top of the remaining portion of the gland.

Inferior and lateral extensions or extrusions. There have been several articles in the literature reporting altogether

between thirty and forty lateral accessory thyroids. I have recently gone over all of this literature and am trying to get

FIG. 7. Lateral extrusion. Thyroid is made up of adenomatous masses. One held out by needle had been extruded and detached with exception of remaining portions of capsule. There was originally more of capsule present than shows in picture, capsule having been broken in handling previous to taking of picture.

later reports on as many as possible. The result of this study will be reported in a subsequent paper, but suffice it to say here that this group can be divided from the reports into (1) atypical thyroid lobes, (2) metastatic carcinoma, and (3) independent thyroid tissue. In our work we have found no inferior or lateral accessory thyroids independent of the thyroid gland, but we have found both extensions, (Figs. 3 and 4) and extrusions (Figs. 5 and 6). The inferior extensions begin usually as an adenomatous mass at the lower pole of one of the lobes. As the mass grows it forges outward from the pole similar to a subserous fibroid of the uterus. As it continues to grow, that portion that has been extruded may grow more rapidly, giving it a pedunculated appearance. As the process continues, it draws out more and more so that the thyroid tissue of the peduncle becomes thinner and thinner

until sometimes the thyroid tissue separates, leaving the mass independent of the thyroid gland except for its connection by the capsule. The capsule may then thin out until there is only a connective tissue band binding the extruded mass to the thyroid gland. I have never found one of these separate masses that was not connected to the main gland at least by the remainder of the capsule, but I do not doubt that it does occur, particularly in those extensions downward into the chest. I believe that those independent thyroid masses found in the chest have developed in this manner. This process of development is similar to the development of the subserous fibroid which sometimes becomes detached and lies in the abdomen free from the uterus.

The so-called lateral accessory thyroids that are non-malignant develop, I believe, in the same manner from either the upper pole or lateral aspect of the lobes. I have seen one instance of a lateral extrusion (Fig. 7) in which the capsule had nearly disappeared and only a thin connective tissue band remained. Had this patient not been operated upon at this time and had the mass later taken on a more rapid growth, this band would probably have given away, leaving it as an independent body which would then have been looked upon as an accessory thyroid.

A study of the embryology of the thyroid gland reveals no method, or mechanism by which thyroid tissue can be produced except from the anlage at the base of the tongue as the existence of other anlage has been disproved. Thyroid tissue may develop from any portion of the thyroglossal stalk. The superior accessory thyroids form from this stalk anywhere from the base of the tongue to the isthmus. They sometimes migrate laterally so that they are not always found in the midline.

Theoretically the stalk might project downwards beyond the isthmus. I have seen small tongue-like projections on the lower border of the isthmus that are

suggestive of this. In one instance (Fig. 3) I thought at first that the extension from the right lower pole might be due to such a continuation of the growth of the stalk, but it was adenomatous and as the extensions or extrusions are usually adenomatous, I doubt this very much.

In operating it is essential that the surgeon remember these anatomical variations, as I have personally seen recurrences in each of the types I have described. The retrotracheal extension is usually, if not always, of the same type as the main portion of the lobe to which it belongs and the extensions and extrusions are usually adenomatous so that the leaving of these means the leaving of masses of pathologic tissue. The pyramidal lobe may show the same pathologic change as the majority of the gland or may be normal. It should not be left, however, even if normal, as it very frequently undergoes hyperplasia following operation if left. I have seen well-marked toxic hyperplastic (exophthalmic) goiter from a pyramidal lobe left at a previous operation.

If all but a very minimal amount of thyroid tissue be removed at operation, if the anatomical variations are looked for and removed when present, if the thyroid gland is saturated with iodine at the time of operation and kept saturated during the period of regeneration (probably two months), and if the patient gets a sufficient amount of iodine thereafter to insure normal thyroid function, there will be no type of surgery giving more satisfactory results than thyroid surgery upon carefully selected, carefully prepared goiter patients.

A NEW AND EFFICIENT RECTAL ANESTHESIA*

AUGUST SPIEGEL, M.D.

BROOKLYN, N. Y.

TWO important events have marked the history of anesthesia during the last century; the introduction of ether and chloroform narcosis and the use of local anesthetics. The latter have not realized the hope once entertained that they would replace the inhalation anesthetics.

From the standpoint of toxicity, it is true that local anesthesia has definite advantages over the more hazardous narcosis. On the other hand, the risk of psychic insult to a conscious patient during a major operation is so great that the majority of surgeons do not dare to expose a sensitive person to such a possibility. Consequently, most operations are still done under general anesthesia. It is hardly necessary to state the disadvantages of the inhalation method. Hence, the attempt to apply the anesthetic by another route than the lungs was quite natural. At present, intravenous injection may be dismissed from consideration because this method has not passed the experimental stage.

Roux was the first (1846) to show that general anesthesia may be induced by injecting water-ether solutions into the rectum. The injury to the mucous membrane of the lower colon and rectum which resulted caused him to abandon the experiments immediately. Not more fortunate was Pirogoff (1847) who gave ether vapor rectally. Consequently, interest in rectal anesthesia declined until revived by Gwathmey. The latter's publication on ether-oil anesthesia by rectum (1913) made the surgical world realize anew the possibility of eliminating the disadvantages of the inhalation method. But reports from various sources refer to severe intestinal irritation, profuse diarrhea, attacks of pain, and sometimes

serious degeneration of the liver cells. Nevertheless, the technical advantages of the rectal method and the fact that the patient is spared the stage of excitement and the risk of postoperative pneumonia, made it worth while to continue the experiments. It was hoped that there might be discovered a preparation with a wide margin of safety which would not irritate the mucous membrane nor increase the danger of general anesthesia, and which would permit the performance of almost any operation. Such a preparation has been recently found in avertin.

Avertin, chemically known as tribromomethylalcohol, was produced by Willstaetter and Duisberg through the reduction of bromal by means of yeast. It is a white crystalline substance, which sublimes easily and has a melting point of 79 to 80°C. In water of 40°C. (104°F.) it dissolves to the extent of 3 per cent. Avertin is sensitive to light and air, and if heated above 40°C., hydrobromic acid is split off and dibromacetaldehyde is formed. The latter product is a severe irritant to the mucous membrane of the colon.

According to the investigation of Straub, the mucous membrane of the colon absorbs avertin more rapidly than water. Consequently, the percentage of the drug in the enema decreases very quickly. To determine the rapidity of absorption, Straub injected a solution of avertin in doses of 150 mg. per kilo of body weight into the rectum of three persons and withdrew the fluid at different times. An analysis of the fluid yielded the data shown in Table 1.

These figures show that in about ten minutes half of the quantity of avertin is absorbed, and after about twenty minutes, three-fourths is absorbed. The

* Submitted for publication November 19, 1929.

TABLE I

| Case No. | Quantity Injected | | Elapsed Time (Min.) | Quantity Withdrawn | | Quantity Absorbed | | | |
|----------|---------------------------|--------------------------|---------------------|---------------------------|-----------------------|-------------------|----------|--------------|----------|
| | Volume of Solution (C.c.) | Amount of Avertin (G.m.) | | Volume of Solution (C.c.) | Avertin Content (Gm.) | Water | | Avertin | |
| | | | | | | Volume (C.c.) | Per Cent | Amount (Gm.) | Per Cent |
| 1 | 305 | 9.1 | 13 | 220 | 4.1 | 85 | 27 | 5.0 | 55 |
| 2 | 360 | 10.8 | 25 | 240 | 1.52 | 120 | 33 | 9.3 | 86 |
| 3 | 300 | 9.0 | 120 | 29 | 0.53 | 261 | 78 | 8.5 | 95 |

remainder of the drug requires considerably more time to be taken up in the rectum, for even after two hours from 5 to 10 per cent can be recovered in the withdrawn fluid. From this analysis it can also be seen that the absorption rate of water is not parallel with that of avertin, but much lower. Furthermore, if after fifteen or twenty minutes complete anesthesia is

cent of avertin in the urine within the first twenty-four hours. Traces were also present in the perspiration, but no bromine could be found in the expired air and feces.

Dosage. To determine the amount of avertin necessary to produce perceptible results, tests were made on rabbits, dogs, cats and mice, and finally on human beings, as outlined in Table II:

TABLE II

DOSE, IN MILLIGRAMS PER KILO OF BODY WEIGHT

| Species | Oral | Intravenous | Subcutaneous | Rectal |
|---------|--|---|-------------------------------------|--|
| Rabbit | 200-300: Sleep 400-500: Sound sleep 60-160: Anesthesia 200: Lethal dose | 50: Sleep 80: Anesthesia 120-150: Lethal dose | 150: Light sleep 500: Anesthesia | 150: Sleep 200: Deep sleep 300-500: Anesthesia |
| Dog | | 120: Anesthesia | | 500: Anesthesia |
| Cat | 100: Anesthesia 150: Lethal dose | 100: Anesthesia | | |
| Mouse | 500: Deep sleep | 120: Anesthesia | 500: Anesthesia | 300-500 Anesthesia |
| Man | 50: Deep sleep | | | 80-150: Sleep— Anesthesia |

not established, there is little chance that it will occur subsequently because of the relatively low concentration of avertin in the unabsorbed solution. However, by individualization of dosage, based upon the physical condition and the constitution of the patient, the writer has never experienced any difficulty in inducing complete anesthesia.

Elimination. Avertin is eliminated by the kidneys and appears in the urine as a glucuronic acid combination which is formed in the liver. Straub found 68 per

These figures demonstrate that in human beings 80 mg. per kilo is enough to induce sleep, but to produce complete anesthesia, 100 to 150 mg. have been given. In the earlier clinical trials, 150 mg. per kilo was considered the standard dose. However, as I have stated before, the best results are obtained by individualizing rather than by adhering to a fixed dose. Time and again, to obtain full relaxation, I have given to children and women of strong constitution as high as 175 mg. per kilo, and to vigorous men as high as

185 mg. without any bad effects. It is now generally advocated that avertin be used only as a basal anesthetic in doses of 80 to 100 mg., supplemented with ether or nitrous oxide and oxygen. I do not favor this method for major operations, although it may prove of value for minor surgical procedures.

Psychological Action. Within four or five minutes after avertin is given, the patient becomes drowsy, yawns a few times, closes the eyes and begins to sleep. In six to seven minutes, the conjunctival and corneal reflexes vanish (a very characteristic sign) and the pupils gradually contract, being narrowed to the greatest extent in ten to twelve minutes. Meanwhile, the muscles relax, the tendon and periosteal reflexes disappear, consciousness is lost and the stage of complete anesthesia supervenes. The effect of avertin upon the respiration is characteristic. As early as two or three minutes after the injection, the respirations become increasingly superficial and less frequent. The patient's face shows a slightly bluish tint and becomes more or less cyanotic after seven to ten minutes. Then automatically, through the accumulation of carbon dioxide in the blood, the respiratory center is stimulated, the rate and volume of respirations increase, the cyanosis disappears, and with very few exceptions the breathing remains normal during the entire operation. In animals, a complete paralysis of the respiratory center has been observed only after very large doses.

A narcotic dose does not produce very marked changes in the cardiac and circulatory system. At first the blood pressure drops from 10° to 15° and the pulse becomes somewhat slower. During and at the close of the operation the rate and volume of the pulse increase and return to the preoperative level, and sometimes even a little above it. An overdose reduces the blood pressure considerably and may be followed by collapse. Avertin has a slight antipyretic action.

Avertin has very little, if any, influence

upon the other organs of the body. When it is given with the necessary precaution the rectal mucous membrane is never affected. That this is true was demonstrated in the psychiatric clinic of Marburg. In this institution 15 maniacal patients were kept in a condition of drowsiness or sleep for two to ten days with avertin without any ill effects, although as much as 200 gm. was administered to some patients in divided doses. However, when avertin solution is overheated or otherwise decomposed, its injection may produce severe injury to the rectal mucous membrane. Several cases of death from this cause have been reported in the German literature. Bacteriologic tests have shown that avertin is strongly antiseptic, *Bacillus coli* and *staphylococcus* being killed in one minute by a 3 per cent solution.

Margin of Safety. The factor of safety in inhalation narcosis is the possibility of immediately suspending administration of the anesthetic and increasing oxygen intake when dangerous symptoms develop. This is impossible with avertin. Once given it would help very little to withdraw the remaining fluid and wash out the rectum in case of ill effects, for absorption takes place very rapidly. The safety of the drug therefore is dependent upon the relatively large margin between narcotic and lethal doses. Comparative experiments on mice with ether-oil and with avertin solution gave the following results: Of 10 mice receiving 0.5 c.c. of 50 per cent ether-oil solution rectally, 2 stayed awake, 6 were anesthetized and died, 2 were anesthetized and survived. Of 10 mice receiving 0.25 c.c. of 3 per cent avertin solution rectally, all were anesthetized and survived. A dose of 0.5 c.c. of avertin solution was necessary to cause death. Hence the lethal dose is twice the narcotic dose.

Preoperative Treatment. The night before the operation, the patient is given a cleansing enema, as it is considered important that the colon be thoroughly emptied.

In emergency operations, as acute appendicitis, this measure has often been omitted by the writer and some German surgeons without bad effects during or after the operation. To secure a good night's rest the patient receives 5 grains of veronal in the evening. Half an hour before the anesthesia, morphine sulphate ($\frac{1}{4}$ grain) and atropin sulphate ($\frac{1}{150}$ grain) may be given.

Preparation of Avertin Solution. Twenty minutes before operation the solution of avertin is prepared as follows: The required dose is weighed out, allowing 150 to 175 (or even 185) mg. per kilo of body weight. The powder is dissolved in enough sterile water at 40°C. (104°F.) to make a 3 per cent solution. These figures may be confusing to anyone not accustomed to the metric system but are easily understood if one remembers that an avoirdupois pound is about 10 per cent less than a metric pound, and that 2 metric pounds make 1 kilo. For example, suppose a patient weighs 129 pounds avoirdupois. This is equal to 129 minus 12 or 117 metric pounds, or 58.5 kilos. Taking 150 mg. of avertin per kilo, multiply 58.5 by 150 equals 8775 mg., or 8.775 gm. To make a 3 per cent solution with this dose requires 285 c.c. of water. After the solution has been prepared, it is tested as follows, to determine whether decomposition has taken place. Pour 5 c.c. of the solution into a test-tube and add 1 or 2 drops of Congo red solution, 1:1000. The avertin solution assumes an orange red color, and any change into blue or violet indicates that decomposition has occurred. If decomposed, the avertin solution should be discarded.

Method of Administration. The patient is placed on the left side, a rectal tube (lubricated with plain vaseline) is inserted, and the fluid is slowly injected into the rectum with a large syringe. During the act of injection, the tube is pushed upwards into the sigmoid, and the patient is advised to take a few deep breaths. This

procedure prevents the expulsion of the enema.

Without a stage of preliminary excitement, drowsiness ensues which gradually deepens into a profound sleep during five minutes. The respiration at first becomes irregular and slower, dropping to about 16 per minute. The face appears slightly cyanotic. In rate and quality the pulse is not materially modified. After fifteen or twenty minutes, if the full anesthetic dose has been given, the patient is completely relaxed and ready for any operation. According to my experience, women are more easily anesthetized with avertin than men or children. In this respect, there is no difference with ether, chloroform and gas anesthesia. Alcoholics require a larger dose.

Postoperative Period. The duration of the operation may be extended to two or three hours without unfavorable reaction. Soon after the operation, the patient awakes, but generally falls immediately into a sound sleep. This lasts from two to three hours and on awaking the patient feels very comfortable, is free from nausea and can take fluids without vomiting. It has also been noted that in abdominal operations there is less tendency to flatulence after avertin than after ether, chloroform or gas. Of course, the patient has to be watched during the entire period of anesthesia, to prevent the tongue from slipping back.

Author's Experience. My observations comprise 200 patients, of whom 100 were anesthetized while I was doing postgraduate work at the University Gynecologic Clinic, Berlin, during 1927. The remaining cases were observed in this country, 33 in my own surgical service and 67 in the service of Drs. W. Bruce Anderson and George Reitz of Brooklyn, N. Y. The character of the latter 100 operations was as follows: appendectomy (acute and chronic cases) 16; vaginal operations (reparative and plastic) 12; gall-bladder operations 12; hysterectomy

11; tonsillectomy 10; removal of ovarian cysts 8; suspension of uterus 5; hernia operations 4; thyroidectomy 4; operations for extensive abdominal adhesions 3; amputation of breast 3; excision of carbuncle (diabetic) 3; vaginal sterilization 2; extrauterine pregnancy 2; cesarean section 1; amputation of leg (diabetic) 1; rib resection 1; hemorrhoid operation 1; exploratory laparotomy 1.

Only 6 of these patients vomited after the operation. In one case, on the day after exploratory laparotomy for a diffuse inoperable cancer of the uterus and intestines, the woman developed paralytic ileus from which she recovered but died three months later. The second case,

amputation of the cervix and vaginal repair, was that of a highly nervous woman who began to vomit after intake of food on the second day. The third case was one of ruptured appendix with localized peritonitis; vomiting persisted for three or four days. The remaining 3 cases were the first in the service of Drs. Anderson and Reitz. These surgeons have been accustomed to give a retention enema of glucose and saline immediately after operation. As avertin is eliminated in the form of glucuronic acid, it seems that the additional glucose produced a certain degree of toxicity, because after discontinuing this practice their patients did not vomit. There were no deaths from avertin.

BIBLIOGRAPHY

Thus far over 80,000 cases of avertin anesthesia have been reported in the German literature, and the enthusiasm for this method is constantly increasing. For American surgeons who may be interested in reading some of the reports of their German colleagues, I refer to the following articles:

NEW INSTRUMENTS

EXPERIENCES WITH A NEW BABY CYSTOURETHROSCOPE*

P. M. BUTTERFIELD, M.D., F.A.C.S.

NEW YORK

EARLY in the work of our Children's Urological Clinic we encountered numerous cases of nocturnal incontinence and occasional cases of frequent urination, all with clear and uninfected urines, which did not respond to the usual methods of treatment. We cystoscoped as many of these children as the parents would permit and in every instance found definite changes at the bladder neck. These changes were thickening, infiltration and cystic masses at the anterior vesical neck with varying amounts of residual urine.

FIG. 1.

The necessity for intimate study and treatment of the child's vesical orifice, and the urethra in its entirety, led us to devise a new instrument for this purpose.

This new baby cystourethroscope is 15 F. in size and has, in addition to a catheter outlet, a slot adjacent to the objective and light through which these areas may be studied and treated. With this instrument we can examine the entire urethra, double catheterize the ureters and use a fulgurating or cutting current.

The vesical orifice findings in 5 cases were as follows:

CASE I. Male, aged twelve, life-long enuresis. Did not respond to the usual measures. Cystourethroscopic examination showed a rough, irregular, thickened anterior vesical orifice studded with tiny cysts.

CASE II. Male, aged five, obstinate enuresis. The anterior vesical neck is thickened and notched. Relieved of enuresis by this procedure.

CASE III. Male, aged eleven, obstinate enuresis. The vesical orifice anteriorly is irregular, thickened and notched.

CASE IV. Female, aged eleven, obstinate enuresis and day frequency. The vesical orifice is thickened, irregular and edematous.

CASE V. Male, aged six, obstinate enuresis. The vesical orifice is thick, irregular and edematous.

This approach to the problem of enuresis is from a new angle. It is suggestive that all cases of obstinate enuresis examined showed definite changes at the vesical neck. These changes are somewhat similar to those found in adults with nocturia. It is also significant that a certain percentage of patients are cured merely by the dilatation of the cystoscopic examination. Further use of dilatation and fulguration is contemplated.

Our interest in this group of cases lies in the fact that 37 per cent of the children applying for care complain of bed-wetting. While it is acknowledged that the condition disappears in the majority of cases after puberty, it is trying for the child from the social aspect and for the mother from the standpoint of added care. It is often of economic importance as many children in orphanages are not adopted by reason of this ailment.

We hope to find through these new studies some common factor in nocturnal incontinence that will be of service in controlling the condition. We have not as yet seen a sufficient number of cases for us to draw any conclusions either as to the cause of these vesical neck changes or as to their relief.

* Read before the Section of Genito-Urinary Surgery, N. Y. Academy of Medicine, May 15, 1929.

CASE REPORTS

ROENTGEN-RAY SHADOW RESEMBLING RENAL CALCULUS CAUSED BY PAPILLOMA OF THE SKIN*

WILLIAM ROBERT DELZELL, M.D.

NEW YORK, N. Y.

THIS brief report is presented to emphasize the fact that papillomata, warts and fibromata of the skin may cast shadows resembling calculi. A characteristic which may help to identify them is that these shadows have extremely sharp margins, due to the fact that they are in contact with the film. Two similar cases were reported by Melicow and Gile¹ in 1927; and Cabot,² Pirie,³ and Holmes and Ruggles⁴ have cautioned us to inspect a patient's back for abnormalities of the skin before referring him for roentgenography.

CASE REPORT

A. G., aged thirty-six, was referred to me to differentiate between a diagnosis of renal and gall-bladder calculus.

History. Chief Complaint, pain in right lower back. Former history negative. Two years ago patient had some pain in left chest and roentgenograms then showed lungs affected by "bad cold."

Present Illness. During past four or five years patient has had pain in right lower back region. Slight pain constantly present and about every six months pain became so severe that patient would go to bed for a week. The pain would then ease up. No nausea or vomiting, no jaundice or blood in stools. There has been some radiation of pain down into right groin. No frequency or dysuria. For past seven weeks pain has been constant and severe and has required constant rest in bed, and has prevented sleep at night.

Cystoscopic Examination. Negative except that the cultures showed a bilateral staphylococcus infection. Functional tests were normal.

Pyelogram Report. Right kidney shadow

is normal in size and a little low in position. Left kidney shadow is normal in size and in fair position. There is a shadow as large as

FIG. 1.

the end of one's index finger in contact with the end of the right catheter, apparently in the pelvis of the kidney. Kretchmer double exposure, the shadow seen moving with the end of the catheter. This shadow is covered by the pyelogram and apparently is in the pelvis of the right kidney, as there is thickening of the shadow in that region. In the erect posture, it is more clearly seen in the pelvis of the right kidney, and is apparently too large to pass. There is a kink of the ureter at the ureteropelvic junction. Suggestion: Removal of stone under regional anesthesia.

No stone was found at operation, so later a papilloma was removed from the patient's back, and roentgenographed. This proved to be the shadow shown in the previous films.

*Read before the Section of Genito-Urinary Surgery, N. Y. Academy of Medicine, May 15, 1929.

Pathological Report (Dr. Dalldorf): Skin papilloma. Specimen consists of two small pieces of yellow fatty tissue covered with from pressure, as it cast a similar shadow when excised, and it was not caused by increased melanin, but was caused either

FIG. 2.

FIG. 3.

what appears to be epithelium. Microscopic study shows the tumor to be a simple papilloma. Melanin is of normal or less than normal amount and there is none found in chromatophores, it being in the basal cell layer entirely. Therefore do not believe pigment can be responsible for roentgen-ray shadow. The stalk is composed of heavy collagen, however, and this may be the explanation.

CONCLUSIONS

1. Skin lesions may cast shadows resembling calculi.
2. The shadow cast by this papilloma was not caused by density of air around it

by the collagen stalk or reduplication of epithelial layers.

3. Stereoscopic plates would be helpful in locating the exact position of doubtful shadows.

KIDNEY RESECTION FOR SACCULATED CALYX*

AUGUSTUS HARRIS, M.D., F.A.C.S.

BROOKLYN, N. Y.

PATIENT, Mrs. E. W., referred by Dr. H. M. Lefferts, thirty-seven years of age, married, consulted me on September 22, 1927 with a chief complaint of persistent gross hematuria.

Family History. Mother died of pulmonary tuberculosis.

Previous Personal History. Hysterectomy performed seven years ago and had not menstruated since that time. Appetite, fair; bowels, regular. Had lost a few pounds in weight. Painless hematuria of short duration and moderate amount noted at intervals since 1917.

Present Trouble. Began about three years ago with profuse hematuria lasting about seven weeks. At that time, she consulted a leading urologist in one of our great Western cities, where she was confined to the hospital for a considerable time, cystoscoped and thoroughly studied. The records of the work done at that time showed practically negative findings throughout, excepting that some lengthening of the upper calyx in the left kidney was noted. From what she could learn, no definite diagnosis was made. Following this, seven or eight renal lavage treatments were given with silver nitrate, which finally controlled the hematuria for a period of almost a year. At that time the bleeding came from the left kidney. Since December 1926, she had persistent attacks of frank hematuria with increasing general weakness. There were no other urinary symptoms nor backache present. She had been confined to bed for the past week with a more severe attack of bleeding and pain in the right kidney region which radiated to the right groin.

Physical Examination. A fairly well-nourished patient, although she was rather pale.

Abdominal examination showed no evidence of renal enlargement or tenderness on either side, or any abdominal masses. The general examination was otherwise essentially negative.

Cystoscopy. This was performed at the Long Island College Hospital on the following day. The bladder was normal; blood-stained urine was seen to come from the right ureter. Ureteral catheters passed freely to both renal

pelves without obstruction, with intermittent return flow of urine from both sides; that from the right was bloody, that from the left, clear.

FIG. 1. Pyelogram of left kidney (taken in 1924) shows slight dilatation of superior calyx. This appears a little less pronounced than our own taken in 1927.

Function tests showed good elimination of phenolsulphonephthalein and urea from both kidneys, although somewhat better upon the right than on the left. There were occasional pus cells. In view of the history, double uretero-pyelograms were taken in the same sitting. These revealed a curious sac-like formation in the upper poles of both kidneys, much more marked on the right than on the left and communicating with an upper calyx. The Wassermann test was negative, and the blood chemistry was normal. There was a leucocytosis of 14,000 with 80 per cent hemoglobin. A provisional diagnosis of hemorrhagic cyst of the kidney was made.

In view of the persistence of hematuria and the duration of symptoms, open operation was advised. In this the patient concurred.

Operation on the right kidney was performed three days later. The kidney was exposed and

* Read before the Section of Genito-Urinary Surgery, New York Academy of Medicine, April 17, 1929.

easily delivered by the retroperitoneal route. The upper pole was found to be distinctly engorged with blood as compared with the

plain catgut were passed behind the edges of the cut surface. The capsule which had been dissected away was then sutured over

FIG. 2. Left pyelogram, September 22, 1927, shows sacculated, elongated superior calyx. Pyelogram almost identical with that taken in 1924.

FIG. 3. Right pyelogram, September 22, 1927, shows sacculated, superior calyx, which was removed at operation.

rest of the organ. As it was thought we might be dealing with a hemorrhagic cyst, no incision was made into this area because of increased danger from hemorrhage. It was considered more advisable to make a clean, transverse, horizontal incision through the entire upper pole at a level of the lower boundary of the sacculated area seen in the pyelogram. The incision, when completed, removed approximately $\frac{1}{3}$ of the kidney substance, and came above the attachment of the pelvis at the internal border. Pressure upon the pedicle aided in control of bleeding, and persistent firm manual pressure with hot lap sponges completely controlled the ooze from the surface while four mattress sutures of No. 2

the raw surface, leaving a small opening for drainage. No sign of a calyx was seen on the cut surface before whipping over the capsule. The wound was closed in the usual manner, with drainage, taking one hour and fifteen minutes for the entire procedure. After removal, the sacculatation in the upper pole was found filled with blood and blood-clot, with the lining membrane distinctly hemorrhagic.

Convalescence was uneventful and she left the hospital, healed by primary union, approximately three weeks after operation. There was slight urinary leakage on the dressing for a few days after operation only. Excepting for a transitory tinge of blood in the urine occurring a short time after leaving the hospital, there

has been no recurrence of symptoms up to the present time, which is approximately eighteen months since the operation. The

calyces. Several small gray-white patches in the cortex suggest tubercles or small abscesses. Microscopic: Tissue is edematous. Along the

FIG. 4. Sketch of kidney showing superior sacculated calyx with dotted line indicating approximate line of amputation.

patient is enjoying excellent health and has gained about 25 lb. in weight. Several urinalyses have also proved entirely negative.

On January 15, 1928, complete cystoscopic examination at the Hospital revealed a normal function of both kidneys, and pyelogram of the right side showed complete absence of the pouch-like area described. There was some rotation of the lower pole away from the mid-line.

A description of the gross and microscopic examination of the portion of the kidney removed is as follows: Gross: The specimen consists of the upper pole of a kidney. The surface is intensely hemorrhagic. On section, the pelvis is dilated and the pelvic lining is thickened and shows small hemorrhagic areas. Pouch-like dilatations extend up into the

FIG. 5. Right pyelogram, January 15, 1928, four months after operation, shows absence of sacculated, superior calyx with some rotation of the kidney, the lower pole away from the mid-line.

cortex are sclerotic areas in which glomeruli are hyalinized and the tubules replaced by fibrosis. Occasional large zones of interstitial hemorrhage are found. The tubules of these areas are filled with blood and occasionally the capsular spaces contain blood. Throughout the tissue, the tubules show marked, cloudy swelling. There is a good deal of infiltration by pus cells, hyperplasia cells and lymphocytes. The lining of the calyces is thickened and infiltrated with large numbers of plasma cells and lymphocytes and occasional polymorphonuclears.

Diagnosis: Subacute Inflammatory Process.

I wish to emphasize the statement of the pathologist that there is no finding of glomerular nephritis.

The report of the radiologist is as follows: "Examination of the K. U. B. tract with opaque ureteral catheters in place on both sides. The catheter on the right side extends up to the upper level of the third lumbar vertebra. The catheter on the left side extends up to the upper level of the fifth lumbar vertebra. Right kidney appears to be normal in size, outline,

and position, no definite evidence of calculi. Left kidney appears similarly normal. Pyelography on the left side shows the kidney

in the upper pole, however, was absent and there was some rotation of the lower pole away from the mid-line.

FIG. 6. Epithelial lining of calyx, showing infiltration of epithelial and subepithelial tissue with subacute inflammatory cells. Epithelium at this point is hyperplastic.

FIG. 7. Showing same changes as in Figure 1, but individual cells are well shown to be (1) clasmotocytes, (2) plasma cells, (3) lymphocytes. In central capillary are margined leucocytes.

pelvis to be well filled throughout. The upper calyx shows a distinct narrowing near its base, while distal to this point there is definite enlargement and dilatation of the calyx. The rest of the calycal markings appear normal. Ureterogram negative. Pyelography on the right side shows a similar constriction near the base of the upper calyx with very marked and definite dilatation and enlargement of the calyx. The upper calycal markings show some blunting and slight clubbing. There is a small constriction in the upper ureter just below the ureteral pelvic junction. Below this, the ureter appears negative except that it is, perhaps, a little larger than is usual. Conclusions: apparently there is a congenital anomaly present, causing a constriction of both upper calyces with some dilatation. This is most marked on the right side. Right side also shows some evidence of old, chronic pyelitis."

Pyelogram of the left kidney, taken in 1924, showed a moderate degree of dilatation of the upper calyx closely similar to the one taken by us in 1927.

The pyelogram taken in January, 1928 showed a similar outline to that taken in the first sitting prior to operation. The sacculation

COMMENTS

After reviewing the English literature, we find the report of a closely similar operation successfully performed by Lower in 1924 for what he termed "hydrocalyx due to infundibular stricture." Persistent renal pain was completely relieved; there was no hematuria. A unique case was reported two years later by Caulk, in which he successfully resected a dense, strictured area blocking a superior calyx with relief of pain and without removing any of the upper pole of the kidney. Almost at the same time that my case was operated on, Papin independently resected the pole of a kidney in two cases for a similar condition. These were reported in 1928.

It would appear as though we are coming more and more to the proposition of successfully employing partial operations upon the kidney. The bugbear has been, chiefly, the risk of secondary hemorrhage, and also, to some extent, the possibility

of persistent urinary fistula. The recorded work which has been done along this line in recent years has been particularly successful, and refinements of technic should soon bring us to a point where these dangers are greatly minimized. Even in horseshoe kidney we find, in a series of 52 heminephrectomies collected by Rathbun, only 8 deaths. These included, also, a number which occurred in the days before perfected pyelographic methods. The blood supply at the time of operation must be carefully studied, especially in the presence of double, fused or horseshoe kidney. The danger of infection in these cases is greater than in single or double kidney.

It is obvious that the diseased portion must be distinctly confined to one segment and that infection may be spread to the remaining portion. For this reason, many failures resulted in the earlier years, when attempts were made to save a part of a tuberculous kidney. It is emphasized by Judd that the incision should be carried through normal tissue, leaving a portion attached to the diseased segment. This seems only logical.

It is possible that, in our case, a wedge-shaped incision may have been employed but, as stated, we purposely avoided this because of the possibility of extensive hemorrhage if we had encountered a hemorrhagic cyst. Dr. Eisendrath recently discussed an instance in which he successfully removed a small sacculated calyx containing a round calculus with a small portion of kidney tissue, by a wedge-shaped incision through the cortex. This suggests also the part that a stenotic calyx may play in the persistence of infection or formation of calculi. Another field for partial resection is the removal of solitary or hemorrhagic cyst. It is possible, also, that this operation may be applied to infected pouch-like areas resulting from the later effects of kidney injury. Young, in 1917, stated that he believed that he performed the first resection where it was deliberately determined to carry out the

operation after pyelographic study, in a case of double kidney. Two years later, Koenig reported a successful case of

FIG. 8. Collecting tubules are dilated and contain blood and pus cells. Lining epithelial layer is flattened. Intervening stroma is hemorrhagic and infiltrated with lymphocytes and scattered leucocytes. Glomeruli are congested and capsular spaces occasionally contain red blood cells.

kidney resection. Numerous cases are also reported by Mayo, E. S. Judd, A. Muller, Rumpel, Eisendrath, Legueu, Herick, Lazarus and others. Herick, in 1920, was only able to collect 5 cases of double kidney resection, 2 of them recorded by Rumpel in 1914. These 2 latter cases had a fistula at the time of the report. Buerger, in 1919, recorded a resection of a double kidney which was partially fused to its opposite fellow. Lazarus successfully employed the operation in unilateral, fused kidney. Results have demonstrated the value of this operation in certain localized lesions of calculus or hydronephrosis.

Sacculations of the lower pole are notably more prone to stasis or recurrence of calculi, and persistence of infection. Judd, in quoting Tuffier's work, gives the statement that it is estimated that a man can live with 80-100 gm. of sound kidney tissue. It is said that Czerny was the first to perform partial resection, in the year 1887. This was done for the removal of a

tumor of the lower pole. Papin, in his new book, presents an interesting outline of historical references concerning partial resection operations.

The collected cases during the early years of renal surgery showed very poor results, but it must be stated that even nephrectomy entailed a very high percentage of mortality. Moreover, neoplasm and tuberculosis were being attacked by

partial resections in a number of instances. These matters are now of historic interest only. We are unable to explain the cause of the hematuria in our case, but it would appear to be associated in some way with the increased intrarenal pressure in the hydrocalyx in the upper pole. It would seem as though varying degrees of hydrocalyx might explain certain vague cases of hematuria.

CASE REPORTS BY DR. A. RAVICH*

BROOKLYN, NEW YORK

ANGIOFIBROLIPOMA OF KIDNEY

The patient, R. N., is a married woman of forty-three having three children. Her family history is irrelevant, and there is nothing significant about her previous history except for an appendectomy twenty-one years ago for acute appendicitis. During the past three years she had been treated for hypertension, headaches, dizziness and for general aches and pains.

The patient's urological history began six years ago with a sudden attack of severe pain in the right lower quadrant radiating upward to the right lumbar region and downward along the outer aspect of the right thigh. This attack continued for about an hour and was accompanied by painful urination but no frequency or gross hematuria. The patient was cystoscoped and roentgenographed at that time and though a diagnosis of right renal calculus was made, the patient gives no

history of ever passing the stone. Since this attack she has had more or less constant pain in the right lumbar region radiating downward along the outer aspect of the right thigh. The pain is dull in character, never very severe and is always aggravated during her menses. There was never any pain on the left side. One year previous to examination she began having diurnal frequency every hour and nocturia four times but no dysuria or hematuria. There had been no loss of weight.

Her first examination at the office on April 20, 1928 showed a rather obese, pasty looking woman with slight tenderness in the left lumbar region and over the upper left ureter. The left kidney was distinctly enlarged. She had a myocarditis with a blood pressure of 210/140. The catheterized urine was slightly hazy, acid in reaction with a moderate trace of albumin but no sugar, and showed several red blood cells, several white blood cells, few

* From the Urological Service of The Jewish Hospital of Brooklyn, N. Y. Read before the Section of Genito-Urinary Surgery, New York Academy of Medicine, April 17, 1929.

amorphous phosphates, one hyaline cast, many colon bacilli and micrococcus urea. Roentgen ray showed the right kidney of normal size but

finally agreed to a compromise of cystoscopy without ureteral catheterization and meatoscopy with indigo carmine. Examination thus

FIG. 1. Roentgenogram showing large left kidney and normal size right kidney with scalloped border.

very irregular and scalloped in outline; the left kidney was considerably enlarged with a cyst like shadow overlying it. No calculi were seen in the urinary tract. (Fig. 1.)

FIG. 2. Pyelogram showing typically irregular pelvis diagnostic of renal tumor.

Owing to the very severe reaction following her cystoscopy of six years previous, she at first flatly refused any further examination but

FIG. 3. Gross cross section of tumor showing kidney tissue above, thick capsule, blood clot and large blood spaces, fibrous and fat tissue.

revealed a slight injection of the bladder mucosa with a slight indentation of the posterior wall of the bladder. A tiny cyst was seen on the roof of the bladder, the trigone was slightly elevated and moderately congested, the left ureter orifice was normal but situated behind the normal position, the right ureter orifice was slightly injected and situated anterior to the normal position. Indigo carmine injected intravenously showed an appearance time of five minutes and +4 intensity from the left ureter orifice and eight minutes with +2 intensity from the right ureter orifice. In accordance with the promise to her, ureteral catheterization was not attempted at this time. In spite of this however, on the following day the patient developed a severe attack of left renal colic which required repeated hypodermic injections of morphine for relief. Her condition steadily growing worse, she was admitted to the author's service at the Jewish Hospital of Brooklyn four days later in a stuporous condition with a typical nephritic appearance. Her blood pressure on admission fell to 130/80, the blood chemistry showed

urea nitrogen of only 20 and a total two hour phenolsulphonaphthalein of 40 per cent.

The patient remained in this stuporous,

the prognosis was regarded as quite hopeless. The possibility of death on the operating table was even considered. In order to improve the

FIG. 4. Low power histological section showing fibrous, fat tissue and vascular spaces.

FIG. 5. High power section showing fat and fibrous tissue.

somnolent state for about ten days, awaking only for short intervals on being aroused. She developed a marked loss of memory and her vision became very poor owing to a hemorrhagic retinitis. During this time her temperature ran up to as high as 104 and she presented definite signs of toxic absorption. Owing to the patient's critical condition, ureteral catheterization was decided upon as a conservative means of relieving if possible any retention of urine in the left kidney. Cystoscopy rapidly done showed a slight injection of the bladder mucosa. A No. 7 F. catheter was easily passed to the left renal pelvis and a few cubic centimeters of highly concentrated, turbid urine was obtained which contained some pus and blood cells with a few colon bacilli. Following this there was a rapid fall in temperature and an improvement in her general condition. A subsequent cystoscopy and pyelographic study performed two weeks later showed a markedly distorted atypical left renal pelvis suggestive of a renal tumor. (Fig. 2.) At this time the author was convinced that he was dealing with a degenerated renal tumor which was causing considerable myocardial as well as general systemic damage by toxic absorption. Her hemoglobin was now reduced to 40 per cent with a red-blood-cell count of 2,300,000. Her condition was progressively getting worse and

condition of the patient sufficiently to withstand operative intervention, a transfusion of 500 c.c. of whole blood was given, and two

FIG. 6. High power section showing fibrous tissue composed of spindle cells, fat spaces and vascular spaces lined with flat endothelial cells.

days later under spinal anesthesia the operation was performed through a retroperitoneal exposure. A very dense and markedly thickened capsule was freed from numerous adhesions

and a large neoplastic kidney with a very thick pedicle was delivered and removed. The lower pole was found ruptured and numerous organized blood clots were found retroperitoneally below the kidney as well as within the kidney capsule. The patient began to improve immediately following the operation, the temperature quickly dropped to normal and the convalescence was surprisingly smooth and rapid. She was discharged from the hospital twenty days following operation with the wound entirely healed, a normal blood chemistry, blood pressure of 184/118 and a urine which showed just several R.B.C., few W.B.C., few granular casts and few colon bacilli, and a total two hour P.S.P. of 36 per cent.

The pathological report of Dr. M. Lederer reads as follows: Macroscopically the left kidney measures $18 \times 14 \times 5$ cm. (Fig. 3). Its surface is covered with a plastic exudate. On section the lower half of the organ is occupied by a degenerating blood clot which has an offensive odor. This clot measures about 14 cm. in diameter and lies between the serous layer of the renal capsule and the cortex of the kidney proper. The cortex is very much compressed and forced into the pelvic spaces, obliterating the entire pelvis. The capsule surrounding this portion of the kidney is very thick and can be discerned as consisting of three definite layers. The outer layer is one made up of fibrous bands and fat; the middle layer consists of a greenish-yellow soft gelatinous substance, and the third layer consisting of fat intermingled with a brownish-grey friable tissue difficult of recognition. The blood clot follows the space between the capsule and cortex to the upper pole where again the kidney tissue is compressed into the pelvis. The line of junction between the clot and the kidney tissue is not clear. There appears to be a zone of nodular structure which is arranged in irregular distribution and with the aid of a hand lens it can be seen to invade the cortex of the kidney for a distance of 1 cm. Microscopically (Figs. 4, 5 and 6) the tumor consists mostly of fat cells of irregular size and shape; together with areas of dense fibrous tissue and some variable sized blood spaces. In the body of the tumor mass are many bloody extravasations with destruction of the neoplastic tissue. Many foci, large and small of fat necrosis, with reactive signs are found. The latter consist of round cell infiltrations and

fat containing large giant cells. The fibrous tissue occurs in large and small masses, and is composed of closely packed long spindle cells. The vascular spaces are found in patches, they are large, irregular in shape and lined by flat endothelium. Diagnosis: Angiofibrolipoma of the kidney with hemorrhage.

Since her discharge from the hospital the patient has been practically free from symptoms except for slight precordial distress on exertion and occasional slight right iliac pain. She has gained considerably in weight since the operation. Her blood pressure ranges around 184/115. Her retinitis had cleared up entirely and her general condition is quite satisfactory.

On March 15, 1929 for the relief of pain in the right lumbar region, which had steadily become worse, a cystoscopy was performed and right ureteral catheterization found a hydronephrosis of 12 c.c. of clear urine. Her two hour P.S.P. at this time was 25 per cent, her blood creatinin 1.8, urea nitrogen 12, uric acid 4.6. Her urine was clear, negative sugar, albumin +2, and contained a moderate number of granular casts, few hyaline casts, few W.B.C., few R.B.C., few epithelial cells and moderate number of colon bacilli.

The interesting features presented by this case are:

1. The great rarity of this type of kidney tumor.
2. The relative lack of symptomatology on the pathological left side until after a simple cystoscopy and roentgenography.
3. The pyrexia and toxemia caused by the degenerating tumor.
4. The striking cure following nephrectomy at a time when all hope for recovery had been given up.

HYPERNEPHROMA IN "PANCAKE TYPE" OF KIDNEY

R. M., a mother of eight children, aged forty-nine years, was first seen on June 14, 1927. Her family history was essentially irrelevant. She had typhus fever as a girl and hemoptysis twelve years ago which she was told was due to heart disease. Three years ago hysterectomy was done for fibroid uterus. One year ago she was confined to bed for twelve weeks with an apparent polyarthritis.

Off and on for several months she had had slight backache. Three days before her first visit at the office the patient was suddenly

vomiting, no chills or fever and no right-sided pain.

Upon examination the patient was found

FIG. 1. Left urogram showing typical hydronephrosis with kinking at ureteropelvic junction.

seized with a severe attack of left renal colic which required a hypodermic for relief. The severe pain however persisted and remained

FIG. 2. Left pyelogram taken on same day as Fig. 1.

localized to the left flank and iliac region. Hematuria, frequency, urgency and dysuria were accompanying symptoms. There was no

FIG. 3. Gross specimen of tumor with kidney flattened around it

to be in fairly good general condition except for a soft systolic murmur at the apex and a slightly palpable left kidney. Roentgenograms also showed a normal right and a slightly enlarged left kidney. In the left pelvis just below the level of the ischial spine there was a small round shadow in the line of the ureter but having the appearance of a calcified gland. Catheterized urine was very slightly smoky and showed many R.B.C., few W.B.C., and was negative for bacteria and tubercle bacilli. Cystoscopy showed slight injection of the bladder mucosa and a long blood clot lying free on the vesical floor behind the trigone. The right ureter orifice was normal, the left slightly congested and blood stained. Intravenous indigo carmine appeared in normal time and intensity from the right orifice but could not be determined on the left side on account of the blood. A No. 6 F. wax-tipped catheter passed up the left ureter to the renal pelvis found a marked obstruction 24 cm. from the orifice and a hydronephrosis of 30 c.c. of dark bloody urine, the evacuation of which was followed by immediate relief of pain. No scratch was seen on the wax tip. A left pyeloureterogram showed a distended renal pelvis and calyces with definite indentation of the ureter just below the ureteropelvic junction which might be caused by an aberrant vessel

crossing at this point. Below this the ureter was slightly distended down to the ureterovesical junction.

FIG. 4. Histological section showing typical hypernephroma cells.

For seven weeks following this the patient felt so well that she failed to return when she was told. At the end of this period she was again suddenly seized with a severe attack of left renal colic accompanied by hematuria and required several hypodermics of morphine. Cystoscopy at this time revealed several small blood clots in the bladder, normal ureter orifices, and a No. 8 F. catheter passed to the left renal pelvis found a hydronephrosis of 32 c.c. of dark bloody urine. Catheterization of the right ureter found several slight obstructions but no hydronephrosis. Careful search for bacteria and tubercle bacilli again proved negative.

Three weeks later she returned feeling fine and without hematuria. The urine was clear and showed just a few R.B.C. Cystoscopy and catheterization of the left ureter found clear urine and no hydronephrosis. Indigo carmine was equally good on both sides. She felt fine until the end of another month when she first noticed a painless hematuria. At this time though the bladder urine was bloody, only

slightly hazy urine and no hydronephrosis were found on catheterization of the left kidney. The blood again ceased and though

FIG. 5. Diagram of *apparent* kink in ureter as seen on anteroposterior radiograph, corrected by lateral view which shows a gentle curve and no kink.

she continued to feel well the patient returned six weeks later for another ureteral dilatation. At this time catheterization of the left ureter again showed clear urine with no hydronephrosis.

Several days later, on November 9, 1927, the hematuria having recurred, she was admitted to my service at the Jewish Hospital for operation. During the next few days while she was being studied her hematuria again ceased. Laboratory tests revealed a normal blood count, blood urea of 16, creatinin of 1.9 and a total two hour P.S.P. of 54 per cent. The red-blood-cell count was 4,500,000 with hemoglobin of 90 per cent, blood pressure 120/88, Wassermann reaction was negative and bacteriological study of both bladder and kidney specimens showed them again sterile. Cystoscopy performed at this time showed clear and sterile urine from the bladder as well as from both kidneys. Definite obstruction was again found 24 cm. from the bladder and a slight hydronephrosis was noted on the left side. Indigo carmine test again appeared +4 from both sides within the normal time limit. Owing to the finding of a very tiny calculus in the bladder at this time, several pyelograms were made with 20 per cent neosilvol to rule out uric acid calculus. A slightly enlarged movable left kidney with distended pelvis and calyces were found. At the ureteropelvic junction there was evidence of a kink which might have been due to an aberrant vessel.

The opposite kidney was normal. At a later date another urographic study revealed the same findings. A very peculiar phenomenon was noted on several of these films, namely, the extreme mobility of the kidney at different exposures during the same sitting, and an apparent horizontal rotation of the pelvic outline with an overlapping of the lower segment of the pelvis by the upper segment as in an elephant's ear. (Figs. 1 and 2.) Feeling very well and no longer having any hematuria, the patient refused exploratory operation and was discharged from the hospital against advice.

One week later she returned with profuse, painless hematuria and at this time consented to operation. Accordingly, on December 1, under spinal anesthesia, the left kidney was exposed through a lumbar incision and found attached by a long thin pedicle and easily brought out into the wound. A pancake type of kidney with a tumor about the size of a tangerine midway between both poles of the kidney was easily removed. The ureter was found to be small and accompanied by a rather large vein and artery. The extrarenal portion of the pelvis was small. The patient made an uneventful recovery and was discharged fourteen days after admission with primary healing of the wound and in excellent general condition. The urine on discharge was clear and essentially negative, normal blood chemistry and a total two hour P.S.P. of 50 per cent.

Pathological report by Dr. M. Lederer showed grossly a pancake type of kidney considerably thinned out, with its pelvis around a tumor, the size of a tangerine.

(Fig. 3.) The tumor was midway between both poles of the kidney which was otherwise normal in size. Histologically the neoplasm proved to be a typical hypernephroma. (Fig. 4.)

The patient was last seen by the author on August 13, 1928 and found to be in excellent condition with clear urine. A similar favorable report was obtained from her family physician several days ago.

This case is presented because of its many misleading signs, the more important of which are:

1. The striking resemblance of the urogram to a nephroptosis with hydronephrosis caused by an aberrant vessel, and the complete absence of the diagnostic pyelographic outline of kidney tumor.
2. The almost invariable cessation of hematuria following ureteral catheterization.
3. Equally good kidney function on both sides.
4. The comparative rarity of this type and location of hypernephroma.

DISCUSSION

DR. LEWALD: I think that without a lateral view of the first case, one could mistake the so-called kink for what would be a gentle curve if one saw it on the lateral aspect. Dr. Ravich called attention to the fact that it was inconstant. I prefer a straight lateral radiograph in a case of this sort. (Fig. 5.) A urologist has demonstrated this experimentally as illustrated.

NON-OPERATIVE TREATMENT OF TALIPES EQUINOVARUS*

H. C. MASLAND, M.D.

PHILADELPHIA

THE case of talipes equinovarus here presented is a text upon which to present a plea for a more exact application of the essential mechanical agencies that will correct this as well as other orthopedic deformities by non-operative means. The history is as follows:

A white girl two and a half years old had a lumbar spina bifida and a meningocele, stated on the hospital records to be the size of an orange. She was operated upon the day after birth. The congenital talipes equinovarus was manipulated during infancy but with the attempt to walk the deformity became more pronounced. She was treated in the

*Submitted for publication June 11, 1929.

orthopedic departments of two of the best hospitals of Philadelphia. A shoe leg brace despite every attempt to adjust it was inefficient as the retracted heel could not be retained in the shoe. The brace turned with the foot upon the leg. The mother was advised that she would have to wait until the child was five years old when an operation would be necessary.

On my first examination, the child stood upon the arch of the foot and the external maleolus. The correction of the deformity demanded that the heel should be under absolute control and rigidly stabilized with the other tarsal bones. Elsewhere¹ I have stressed the virtues of plaster-of-Paris casts, without padding and properly conceived and properly applied to give a control in the reduction of fractures beyond the ability of any other material. The same principles will apply in many orthopedic deformities.

This child's foot was diminutive and plaster bandages, dripping wet, 1 in. wide and 2 yds. long, were applied to form a plaster slipper, leaving the toes bare. The tarsal bones were pliable and the foot was held in normal position except the retracted os calcis. The bandage was applied without tension but moulded around the ball of the heel and tarsal and metatarsal bones, leaving sufficient clearance for the flexing of the ankle joint. It should be applied daintily and moulded quite wet to the varying contours of the foot. When such a cast is properly applied, the plaster being smoothed into the mesh of the bandage, it has a skin surface as smooth as the skin itself.

A small s-shaped hook attached to a string was imbedded in the cast. In Figure 1 it is shown on the outer side of the foot. In a later replacement, I placed it on the dorsum of the foot behind the second phalangeal interspace.

The leg cast was similarly applied to the limb with a hook imbedded in the plaster on the outer side. The cast as first applied would not turn on the leg, with but the subsequent increased activity of the child, it slipped down over the poorly developed calf muscles. It was replaced with a cast extending from the popliteal space to the maleoli. This was retained. After the first cast was applied the child stood for the first time in its life on the sole of its foot and has so continued to do. It will be noticed in the illustration that there

is over correction of the varus deformity. This was produced by placing a small metal strip along the outer side of the sole with the ends

FIG. 1. Elastic traction to overcome shortening of tendo achilles; immediate ability to walk with application of this plaster cast brace.

buried in the cast. I believe that this over-correction is beneficial in walking. The metal strip also prolongs the life of the cast. An elastic band was stretched between the foot and the leg hooks. This should be strong enough to exert a slightly greater continuing tension than the tonal pull of the calf muscles. Great tension might cause the cast to cut the wrinkled skin at the flexure of the ankle joint.

There have been no complications. The child has become an irrepressible walker. After six weeks the tendo Achilles was fully restored to normal length.

The casts should be changed in from six to eight weeks to allow for growth of the parts. Undue wear and other indications might call for a more frequent change. There is not the slightest doubt that the foot can be retained in normal position until the ossification of the bones makes the shape permanent. The recuperation of the damaged muscles and nerves is uncertain. It is quite likely that some form of brace may be required for life. A regula-

¹ Fracture fallacies and some suggestions. *Internat. J. Med. & Surg.*, March, 1929.

tion brace is more durable and less troublesome. It will be applied just as soon as the size of the foot and other conditions insure its efficiency.

It is my conviction that these talipes cases, even congenital dislocations of the hip, can be corrected better than has been done by these graduated but persistent traction methods. Of course this requires an exact comprehension of the mechanical details necessary for success. In meeting these mechanical requirements, I believe that there is nothing that can compare with a plaster-of-paris cast carefully planned and properly applied. It can be laid to escape or include important areas. Applied next the skin, its smooth surface

grips but does not strangulate. Swelling is not a factor here as in fractures where the cast may have to be split and opened some.

The hygroscopic qualities of the cast absorb and dissipate the moisture, thus preserving a dry skin. Fitting snugly, it will not rub and chafe the skin. Where an edge of the plaster might cut the skin, the skin can be protected with an underlying cuff of artificial leather. Proper supervision is to be expected. My plan is to see the patient the day after applying the cast brace, then in a week and then two weeks, always with positive injunctions to return at any time that the slightest occasion for concern might arise.

SUPPURATIVE MYOSITIS OF THE PSOAS ILIACUS SUGGESTING RENAL PATHOLOGY*

W. F. MCKENNA, M.D.

BROOKLYN, N. Y.

PSOAS abscess is ordinarily considered as of tuberculous origin. In the majority of instances this is undoubtedly true. Whether the case described hereafter was tuberculous in nature has not been absolutely disproved, but the weight of clinical and laboratory evidence was against it. Myositis is well recognized, and suppurative myositis has been frequently observed. Given reported a small series of suppurative psoas myositis cases in 1922, and gave references in the literature to others.

The patient was a woman of thirty-three, married, and the mother of three children. She had always enjoyed good health, and showed no signs of any chronic illness before the present trouble began. Seven weeks before her admission to the hospital she had what she and her family physician described as an attack of grippe from which she made an apparently uneventful recovery. At this time she had a mild fever, and the generalized body pains and

aches so commonly described in this condition. About one week after recovery she had an attack of sharp pain in the right lower quadrant which was thought to be appendicitis, but it disappeared within twenty-four hours, and she again felt perfectly well. About two days after this there was an acute attack of pain in the region of the right kidney. This subsided, but before it had entirely disappeared a similar pain occurred in the left kidney region. This, too, subsided within twenty-four hours, but recurred at the end of three or four days and remained constant for the next four weeks. During this period she had a febrile movement daily to 101° or 102°F. The pain was localized almost exactly over the left costovertebral angle, and was sometimes intense. Her physician said there was always exquisite tenderness at this point. Urinalysis showed large amounts of pus and bacteria, but the specimens were not catheterized.

Seen at her home twenty-four hours before admission the picture presented was certainly suggestive of renal pathology, and a complete urological survey was advised. Except for the

* Read before the Section of Genito-Urinary Surgery, New York Academy of Medicine April 17, 1929.

very definite localization of the pain, and the temperature, the usual bladder symptoms were lacking. The patient kept the left knee flexed

the region of the kidney with the thought that a perinephritic abscess might be present.

The usual kidney incision was made through

FIG. 1. Haziness of left psoas outline in contrast to very definite outline on right.

FIG. 2. Definite bulging of left psoas outline three days after Figure 1.

at all times and was unable to lie upon the affected side.

The cystoscopic findings after admission were essentially uninformative, as the bladder showed no evidence of disease, and the function of each kidney was normal, and no pus was found in either the bladder or kidney urines. The roentgenograms were of considerable value. As can be seen from the pyelogram plate (Fig. 3) the left kidney is displaced from its usual location, and pushed somewhat upward and to the left. The lumbar spine curves slightly to the right, and a haziness over the region of the left psoas is apparent. At this time both the medical consultant who first saw the case and myself thought that the kidney was not the site of any pathology, but that a retroperitoneal abscess involving the posterior lymphatics or the muscle layers was present. A differential blood cell count showed only 10,200 leucocytes with polymorphonuclear cells of 79 per cent, and as the patient felt somewhat better, and her temperature had receded somewhat the surgical consultant advised against operative measures. The patient was kept under observation for three or four days, but as there was no improvement in her condition, it was decided to explore

FIG. 3. Displacement of left kidney outward and upward. In all three figures slight curvature to right is noticeable.

the skin and fascial layers. Upon approaching the muscle layer the external oblique and internal oblique were incised at their thinned-

out portions, and pus was found. There was still a thickened layer of swollen and congested fascia which was not incised, and the kidney could not be palpated beneath it. This layer was felt to be the transversalis fascia, much distorted by the inflammatory process extending from the deeper part of the abscess. If such were the case the suppurative process had extended by continuity from the psoas sheath along the sheath of the quadratus to the transversalis.

The cultures from the pus were *Staphylococcus aureus*.

The patient made a smooth convalescence, and was discharged from the hospital about two weeks after operation with a small draining area.

The patient can walk easily, has no pain, and can use the left leg as well as the right.

The principal interest in this case lies in the somewhat rare underlying pathology, the suggestion of either a renal or perirenal lesion, and the unusual site in which the abscess was apparently pointing. There was no sign of pointing in the groin or loin, and no mass or point of tenderness existed except at the costo-vertebral angle.

In the cases so well described by Given the abscess gave signs of pointing in the groin, and these cases as described by him were opened in the lower abdomen, and drained through an extraperitoneal incision. There was no evidence of any lesion of the vertebral column noted except the slight curvature to the right which was probably due to spasm of the erector group.

URIC ACID CALCULI*

FEDOR L. SENGER, M.D.

BROOKLYN, N. Y.

THE literature on the less dense urinary calculi is rather meager, there being very little written beyond an analysis of the stones and statements of their percentage of incidence. Recently we have had on Dr. Read's service three cases over a period of four months, rather a large number even in a fairly active urologic service.

Swain in 1897¹ made the observation that urinary stones of varying chemical compositions had a marked difference in penetrability to the roentgen ray. He placed calculi directly on the roentgen-ray plates and exposed them from one to sixteen minutes. He observed that the more dense the stone, the deeper the resultant shadow. He tabulated his results as follows, according to density of shadow. Stones composed of:

1. Calcium oxalate.
2. Calcium phosphate.
3. Uric acid.

¹ Bristol M. J.

* Read before the Section of Genito-Urinary Surgery, New York Academy of Medicine, April 17, 1929.

Cystin xanthin and cholesterin are also less dense than bone (ribs).

He also made the interesting observation that the longer the exposure to the rays the less dense the resultant shadow, so that at the extreme limit of sixteen minutes' exposure only the calcium oxalate stones cast shadows on the negative. He definitely drew the conclusions that for accuracy in diagnosis short sharp exposures were the best, which even today with our improved technic is still true.

Some cases have been reported in which these less dense stones show areas in pyelograms of greater transparency than the opaque media 12 per cent iodide, giving the suggestion of a non-opaque stone.

A report of my cases follows:

CASE 1. Adult male, aged fifty years, admitted September 24, 1928. His admission diagnosis was tumor of the kidney, due to the presence of a large palpable mass in the left kidney region.

His previous history is entirely irrelevant except that he had noticed the mass in his side for about six or seven months. He had never had any urinary symptoms except some night frequency, and never any colicky pains. His urinary examination showed some microscopic blood and pus cells, but otherwise clear urine.

Cystoscopy: Catheters passed to the left and right kidney pelvis easily, but no urine was recovered from the left side at all, the right side gave us normal urine and normal function.

The left pyelogram shows a definite arresting of the solution at the pelvic ureteral junction with just a suspicion of a little of the media trickling up to the pelvis. We repeated this at several sittings with the same result in each instance. Accordingly we made a diagnosis of renal tumor, with filling of the pelvis and advised operation.

At the time of operation we were greatly surprised to find a large pyonephrotic kidney with a stone blocking the ureter completely and the kidney full of pus and small stones and debris, none of which show in our plates. We took the specimen to our roentgenologist who placed it directly on a plate and took several exposures of different durations and even this failed to show these calculi very definitely.

Mr. Steel of the department of chemistry analysed these stones and reported them to be pure uric acid plus some fats and other organic matter. Another quite remarkable feature is the entire absence of pain during the blocking and destruction of this kidney.

CASE II. Adult male, aged sixty-one, with prostatic obstruction.

During a routine cystoscopy we found three smooth yellow stones lying in the base of the bladder. These looked like ammonium urate stones, and with our previous case in mind we decided to roentgenograph them. The resultant picture does not show any stones.

We then did a cystogram with iodide. Still no stones. But the air cystogram showed them up beautifully.

The chemical analysis of these stones showed ammonium urate around a nucleus of uric acid.

This air cystogram suggests to me the possibility of doing air pyelograms for diagnosis in uric acid stones of the kidney pelvis.

CASE III. Mrs. J. S., aged forty-six, admitted November 30, 1928, complaining

of painful urination, with frequency and cloudy urine. Her history dates back over a period of years, with an indefinite sense of something wrong in her left side.

The bladder urine was full of blood and pus cells.

Cystoscopy: Both ureters easily catheterized, the right side being clear and normal, as regards function and urea. On the left side the urine was pusy. The appearance time of the phthalein delayed for nine minutes, and urea lower than normal.

On checking up the pyelogram we noticed that in the kidney pelvis there was an area less dense than the media encircling it and concluded that we had a uric acid stone in addition to pyonephrosis.

At operation this stone was removed by pyelotomy and on analysis proved to be uric acid.

Before this patient left the hospital we dilated her ureter and collected urine from this side. This urine contains a large number of uric acid crystals.

We did the same thing on the bladder urine from the previous case, letting it sediment, and found that it also contained large quantities of uric acid crystals, in all the characteristic shapes, with stones in sheaves and rosettes.

We are trying to keep the urines in these cases neutral or slightly alkaline in the hopes of avoiding future trouble.

DISCUSSION

DR. L. T. LEWALD: The question of uric acid calculi constantly comes up in roentgenological work. The combination in the last case of the three stones in the bladder together with the sodium iodide, plus air, offered a contrast such as we now get in tetraiodide examination of the gall bladder. It was the coating with sodium iodide that helped to make the very beautiful demonstration.

DR. A. RAVICH: During the past few years I have found urography with 20 per cent neosilvol of much value in outlining uric acid calculi in the renal pelvis and ureter. I have a number of films which show these stones beautifully. These would otherwise be overlooked if sodium iodide were used as a pyelographic medium.

DR. SENGER: We have tried Dr. Ravich's method with neosilvol, using varying percentages of solution, but have not been able to outline anything satisfactorily with this.

DEPARTMENT OF RADIOLOGY

JAMES T. CASE, M.D., F.A.C.S., EDITOR

CLINIC ON MALIGNANT DISEASES MEMORIAL HOSPITAL, NEW YORK

PRESENTED BY THE STAFF OF THE MEMORIAL HOSPITAL, SEPTEMBER, 19, 1929

INTRODUCTION

DOUGLAS QUICK, Chairman

IN the two hours at our disposal we shall attempt to give you a comprehensive insight into the routine work of our institution. Our work is limited to the study and treatment of cancer and allied diseases, so that we shall deal with therapy rather than diagnosis. Each of our clinical departments, except that one which we choose to term the department of medical malignant diseases, is under the direction of a surgeon who is completely responsible for the treatment of the case throughout, whether that treatment be surgical or radiological. We regard the treatment of cancer as being essentially a surgical problem. We believe that the best interests of the patient are served by having the entire treatment of that patient under one directing head, with adequate interdepartmental consultation, of course. Our clinical organization consists of a number of departments, each under the direction of an attending surgeon trained not only in his surgical specialty but radiologically as well. The departments are all correlated by a clinical director.

In arranging our program for this clinic we have attempted to select topics which, we hope, will give as wide a range of problems as possible and our methods of dealing with them.

GIANT-CELL TUMORS OF BONE

WITH SPECIAL REFERENCE TO TREATMENT
TECHNIC

R. E. HERENDEEN, Roentgenologist

CASE I. *Giant cell tumor of the radius.*
A. F., male, aged eleven, admitted October 8, 1927.

History of two injuries to the left wrist in the past ten months, followed by pain and swelling. Treatment was by massage and splints, and following a biopsy, by incision, chemical and thermal cautery, and bone graft.

Examination showed a hard bony tumor in the left forearm, expanding the bone and causing a swelling about three times the size of the normal bone. X-ray films confirmed the findings of an active recurrence with absorption of the bone graft.

Microscopic examination (of specimen from former operation) showed a giant cell tumor of cellular but benign type.

Treatment consisted of high voltage x-rays, and succeeding films demonstrate the satisfactory response, and the patient's present condition.

CASE II. *Giant cell tumor of the os calcis.*
E. C., aged five, admitted November 6, 1924.

History of sudden onset of pain in the foot two and one-half years ago. The pain and swelling have grown worse in spite of various treatments, including immobilization brace and splints. At present the greatest circumference of the left ankle is 30 cm., as compared to 21 cm. of the right ankle.

Treatment was by low and medium voltage x-rays over a period of four months.

Succeeding films demonstrate the condition of the os calcis at the first visit here, and the improvement subsequent to x-ray therapy.

CASE III. *Giant cell sarcoma of the right humerus.*

A. U., female aged sixty-five, admitted October 24, 1924.

History of "fever" and pain in the right shoulder and elbow of six months' duration, with limitation of motion.

Examination by x-ray films demonstrated a destructive process in the distal end of the humerus.

Treatment by x-ray therapy was followed by subsidence of the swelling and disappearance of pain. The roentgenograms demonstrate the amount of repair.

About two years later a similar process developed in the ascending ramus of the right inferior maxilla, and since that time, during the past three years, at irregular intervals, similar tumors have appeared, some bone and some in the soft parts in various areas widely scattered over the entire body. Response to radiation is always the same as was obtained in the treatment of the primary tumor.

The patient's general condition has improved and has been excellent during the past five years, excepting for short periods during the development of new tumors.

TYPES AND TREATMENT OF BONE SARCOMA

WILLIAM B. COLEY, Attending Surgeon

Two definite types of bone sarcoma are included in the cases presented: the osteogenic and the endothelial myeloma (Ewing's sarcoma). The osteogenic type associated with considerable new bone formation has been found both extremely radioresistant and also rarely curable by amputation. Amputation followed by prophylactic treatment with the mixed toxins of erysipelas and *Bacillus prodigiosus* has, in the speaker's hands, given far better results. This method was employed in Case v as well as in a series of 40 cases of osteogenic sarcoma including the endothelioma type, but excluding the giant-cell,

in which a study of the end-results showed 50 per cent of the patients to be alive from five to twenty-five years.

Cases IV and VI, here presented, show what can be accomplished by a combination of toxins and radiation in far-advanced and inoperable stages of the disease. In both cases, generalization had taken place, and the x-ray plates showed evidence of pulmonary metastasis in both. Case IV indicates that the endotheliomatous type of bone sarcoma should rarely be considered entirely hopeless.

At the Memorial Hospital during the past twelve years, practically all cases of primary operable sarcoma of the long bones, of all varieties, have been treated by radiation as the method of choice. The reason for this lies in the fact that the Memorial Hospital is fundamentally a research institution, and it was believed important to determine what can be accomplished by radiation in these cases. An analysis of the end-results in 1928 showed that of 92 cases of primary operable sarcoma of the long bones (exclusive of giant-cell tumors) in which radiation had been employed as the primary method of choice, 45 had developed metastases while undergoing treatment, and in most cases while the local condition was showing more or less evidence of improvement; all of these had died. In 45 cases, amputation was performed after varying periods (two months or more) of irradiation. It was thought by some of the members of the staff that even in cases of failure to control the disease, preliminary radiation before amputation might yield better final results. In the group so treated, only 3 were known to be well for five years. In other words, this method does not yield so good results as does early amputation alone. At the International Cancer Conference in London, July 1928, Dr. Ewing stated that early amputation is the best method of treating osteogenic sarcoma of the long bones; to this, I would supplement a prolonged course of prophylactic toxin treatment.

In the endothelioma type of bone sarcoma, which has been found to be highly sensitive to both radiation and toxins, attempt to save the limb should be made in practically all cases. In those in which amputation has to be employed, a prolonged course of prophylactic toxin treatment should be given. In osteogenic sarcoma of the long bones with marked new bone formation, early amputation without preliminary radiation is, at present, the method of treatment at the Memorial Hospital.

Giant Cell Tumors. Although the Memorial Hospital is the first institution to demonstrate the possibility of curing cases of giant-cell bone tumor by radiation alone, and in spite of the fact that Dr. Herendeen can show some very remarkable results in treating this type of tumor of the long bones by radiation, there is still a doubt that this is the method of choice, first, because of the longer period of disability entailed, and second, the difficulty of making a correct differential diagnosis between benign giant-cell tumor of the long bones and malignant tumor. At the Memorial Hospital it has been found impossible to make a correct diagnosis in 1 out of 4 cases: in many cases of supposed benign giant-cell sarcoma treated by radiation without biopsy, it has been revealed later that the condition was really malignant and that metastases had developed before the true nature of the tumor had been recognized, with the result that the chance of saving the patient's life by amputation had been lost.

Bloodgood has shown that a very large proportion of giant-cell tumors may be cured by curettage, although in a certain number of cases, especially those with disease involving the lower end of the femur, amputation may finally have to be performed. In my opinion the present method of choice in the treatment of giant-cell sarcoma of the long bones is a very extensive curettage, swabbing out the cavity with zinc chloride or pure carbolic acid, followed by a two or three month

period of toxin treatment. A number of my most brilliant results have been obtained with the toxins alone, without curettage.

The question, however, as to the best method of treatment of giant-cell sarcoma is still unanswered; further study of a much greater amount of material is required before any hard and fast rules can be laid down.

CASE IV. *Periosteal sarcoma (endothelioma type) of fibula with metastases to groin, abdomen, and possibly, lungs.*

H. S., male, aged eight, first seen in consultation, June 1920, admitted, October, 1920.

History of injury to leg January 1920, after which pain and swelling, apparently of bony origin, developed. Clinical and roentgenographic diagnosis was osteomyelitis. In March, 1920, an exploratory operation revealed some pus and marked thickening of the bone, which was extensively curetted. Microscopic examination showed the disease to be periosteal sarcoma of the endothelioma type. After operation, the tumor grew with great rapidity.

Examination in consultation showed the lower two-thirds of the fibula occupied by a large tumor, apparently of periosteal origin, fungating in the central portion. The glands in the groin were enlarged, one to the size of an English walnut.

Treatment consisted in immediate amputation followed by toxins.

Pathological report by Dr. F. M. Jeffries was round-cell sarcoma of periosteal origin; by Dr. Ewing, endothelioma.

Toxins were given daily to the point of producing a marked reaction, after which injections were given only every other day; the glands in the groin decreased somewhat in size but did not disappear. In July 1920, a gland was removed and the microscopic examination showed round-cell sarcoma. The toxin treatment was kept up until the middle of August. Re-examination in October 1920, showed the inguinal glands increased in size, and a hard mass, the size of a child's head, in the right iliac fossa, evidently involving the retroperitoneal glands. A roentgenogram of the chest showed well-developed unquestionable metastasis to the lung.

Treatment at Memorial Hospital, where the child was admitted in October 1920, consisted in 10,109 mc.-hrs. of radium at 7 cm. distance.

The child was then taken home as a hopeless prognosis had been given. There were no further toxins or radium treatments. In May 1921, a letter was received stating that the patient was apparently in excellent health and going to school regularly. He returned to the Memorial Hospital in September 1922, and a careful examination failed to reveal any evidence of tumor in the abdomen or the groin, and a roentgenogram of the chest failed to show any evidence of pulmonary metastasis. The patient has remained well up to the present time, nine years later.

This is case No. 267 in the Bone Sarcoma Registry. The diagnosis of that committee was Ewing's tumor.

CASE V. *Extensive periosteal osteogenic sarcoma of the lower end of the femur. Amputation and prolonged toxin treatment.*

S. D., female, aged eighteen, admitted to the Hospital for Ruptured and Crippled, March 1906.

History of pain in the right knee early in 1905; in August a plaster splint was applied and worn for nearly seven months, during which time the patient had become emaciated and bed-ridden.

Examination showed a fusiform swelling of the right knee just above the joint, with a circumference 5 inches greater than that of the opposite side. Roentgen-ray examination showed the lower 6 inches of the femur nearly twice the normal thickness.

Treatment began with an exploratory operation (Drs. Gibney and Coley) which revealed what was believed to be a sarcoma, and was followed by immediate amputation. The patient was then put upon the mixed toxins, with injections increased to the point of producing marked reactions. Almost immediate improvement followed, with increase of the patient's weight from 69 lb. on June 2, to 92 lb. on October 28. She has remained well up to the present time, over twenty-two years.

In this case, the diagnosis made by Dr. Jeffries, pathologist of the Hospital for Ruptured and Crippled, was osteosarcoma, mixed cell (no giant cells). Dr. Ewing examined a section sometime later, and made a diagnosis of malignant osteogenic sarcoma. This is the diagnosis that was made by the Bone Sarcoma Registry (Case No. 408).

CASE VI. *Sarcoma (angioendothelioma type) of the tibia and fibula with multiple metastases to the lungs.*

C. P., male, aged twenty-eight, admitted August 1924.

History of pain in the upper end of the left fibula, July 1923. One month later a smooth mass, the size of a lemon, was found at the same site, and shortly after, a distinct bruit was heard on auscultation. A diagnosis of aneurysm of the popliteal artery was made, and the tumor was removed, September 1923. Roentgen-ray treatment was begun at once. In August 1924, the patient complained of severe pain and weakness in the upper end of the fibula, and at the same time, a swelling was noticed in the lower end of the tibia.

Examination at the Memorial Hospital showed the upper end of the left fibula to be the site of a globular, pulsating, tense tumor, measuring 5 cm. in diameter. Over the anterior portion of the left tibia, at the junction of the middle and lower thirds, a large swelling measured 8×5 cm. A roentgenogram of the tibia showed a central tumor, practically destroying the tibia for a distance of 3 or 4 inches. A roentgenogram of the chest showed distinct evidence of metastasis to the lungs. The clinical diagnosis was recurrent sarcoma of the fibula, with metastases to the tibia and the lungs.

Treatment between August 20, 1924 and December 20, 1925, consisted of twenty-five high-voltage roentgen-ray exposures, each of eighty minutes' duration; fourteen were given over the chest, and eleven over the tibia and fibula. The disease was kept under fair control until the summer of 1925 when the tumors of the tibia and of the lung showed evidence of increase in size. The patient was re-admitted and toxin treatment begun; in September 1925, examination showed some regression of the tumors, a gain in weight, and improvement in the general condition. Toxin treatment was resumed, February 1926. Frequent roentgenograms showed no increase in size of the metastatic tumor of the lung.

The pathological fracture, however, had never shown any tendency to union, the leg was kept in a splint and was entirely useless, so amputation was performed by Dr. Bradley L. Coley in June 1926.

Pathological report by Dr. Ewing was angioendothelioma, very bizarre structure. Dr. Ewing's previous diagnosis on the specimen removed from the soft parts of the calf was angioendothelioma of bone or metastatic renal carcinoma.

Since amputation, the patient has remained in good condition. Another course of toxin treatment has been given. There is no evidence of increase in size of the tumor of the lung.

This case is remarkable, first, because of the long period during which the extensive metastases of the lungs have been kept under sufficient control (first by roentgen rays alone, and later by roentgen rays and toxins); and, second, because of the very large amount of roentgen rays that were used without apparent harm.

This is case No. 574 in the Bone Sarcoma Registry. The diagnosis of that committee was metastatic hypernephroma.

THE MALIGNANT GRANULOMAS

LLOYD F. CRAVER, Attending Physician

Out of the vast collection of diverse clinical pictures embraced in the term malignant granulomas, 2 cases illustrating involvement of tissues in or about the mediastinum are selected for presentation. One is a case of probable Hodgkin's disease of the hilal lymph nodes; the other, Hodgkin's disease of the thymus.

These cases illustrate the fact that occasionally Hodgkin's disease begins or, at least, first manifests itself in or about the mediastinum, and may remain for a considerable time fairly well localized to that region. The same is true of lymphosarcoma.

Of the tumors of the thymus (thymomas), by far the most frequent type is that which is very radiosensitive, thymic lymphosarcoma. Yet, occasionally a tumor presenting all the clinical and roentgenographic features of thymoma proves to be radio-resistant. Several of these, at autopsy, have been found to be thymic carcinoma.

It has seemed possible to foretell the radioresistance of some of these tumors on a clinical basis. Patients with such radio-resistant growths are likely to present a striking network of dark veins on the chest wall, an evidence of more marked venous stasis than appears in most of the thymomas; also, if the supraclavicular or axillary nodes are involved, they are stony hard. Such cases usually have considerable stridor.

On the other hand, those cases of thymoma which have shown penetration of the chest wall and production of sternal or parasternal tumors have, as a rule, been found to belong in the class of very radio-sensitive tumors. An exception is noted in the second case reported, a thymic Hodgkin's disease only moderately responsive to repeated heavy radiation.

Satisfactory treatment of these deeply situated intrathoracic tumors requires radiation of a penetrating type, such as is furnished by the high-voltage x-ray machines at 175 to 185 k.v. with 0.5 mm. Cu filter at a distance of 50 cm., or the radon or radium element pack filtered through the equivalent of 2 mm. brass at a distance of 10 to 15 cm. The dosage must depend upon several considerations, not the least of which is the patient's general condition. Best results are obtained by attempting to secure long palliation. Overdosage in an attempt to cure may either damage the skin so as to prevent necessary subsequent treatment, or may depress the patient's general condition to such an extent that the desired palliation is defeated.

CASE VII. *Mediastinal tumor.*

S. R., male, aged sixteen, admitted April 1928.

History of frequent epistaxis for many years, with recent more acute onset of hemoptysis, apparently following gripe.

Examination by x-ray films showed hilal masses. Diagnosis questionable; probably Hodgkin's disease of the hilal nodes.

Treatment began April 1928 with an exposure of 300 ma. min., 1.5 mm. Cu, 175 k.v., 50 cm. target-skin distance over each hilus anteriorly. The response was unsatisfactory. In June 1928, an exposure with the same factors was given to each hilus anteriorly and posteriorly, a total of four exposures. In September 1928, by the radon pack, 20,000 mc.-hrs. at 10 cm. distance were given the mediastinum anteriorly.

The results have been a gradual reduction in the hilal masses. The patient is in excellent general condition, has gained weight, feels well, and has been swimming all summer.

CASE VIII. *Mediastinal tumor.*

P. V., male, aged nineteen, admitted March 1928.

History of pain in the left arm, fourteen months previously; tonsillectomy was performed for a supposed neuritis, with a partial relief of pain. Shortly after, a swelling appeared over the sternum; this was treated by x-radiation, elsewhere, for three months without regression.

Examination showed bulky masses in the mediastinum, the chest wall, and in both cervical regions with moderate enlargement of the axillary nodes. Otherwise, the patient was comparatively symptom-free.

Pathological report on a supraclavicular node was thymic tumor, granulomatous, of large cell type.

Treatment from March to July 1928, consisted of 20,000 mc.-hrs. at 10 cm. distance, to each side of the neck by the radon pack, and of 40,000 mc.-hrs. at 15 cm. distance to the mediastinum anteriorly, a total of thirteen exposures. Also, from June 1928 to September 3, 1929, twenty-seven exposures have been given of high-voltage x-radiation, mostly at 50 cm. target-skin distance, some at 30 cm. distance, 185 or 175 k.v., 0.5 mm. Cu, and 140 to 360 ma.-min., depending upon the distance factor, to the mediastinum anteriorly and posteriorly, to the neck, and the chest wall masses.

NEOPLASMS OF THE VULVA

WILLIAM P. HEALY, Attending Gynecologist

In the 3 cases reported herewith, 2 of carcinoma and 1 of epithelial papilloma, it is of interest to note that in each instance the neoplasm developed on a pre-existing skin lesion. All the cases gave a history of pruritus vulvae and all had leucoderma with marked thickening of the skin of the vulva.

Practically all cases of epithelioma of the vulva are histologically of the adult, fully developed squamous variety of cancer cell and, therefore, are relatively radioreistant. For this reason a heavy or caustic dose of ray therapy must be applied in order to cause the disappearance of the lesion. As the inguinal glands in practically all instances are involved on one or

both sides, both groins should also be heavily irradiated. When the reaction from this treatment has subsided, we are in

FIG. 1. Case VIII. N. W., #35796. Papillary ulcer 3.5 cm. in diameter. Smaller ulcer 0.5 cm. in diameter below large one. Well marked leucoderma.

favor of vulvectomy with dissection of one or both groins. We feel that this combination of heavy radiation followed by radical operation offers the patient the best chance of cure.

CASE VIII. *Primary carcinoma of the vulva.*

N. W., #35796, married, nullipara, aged fifty, admitted February 21, 1926.

History of gradually enlarging sore on the vulva of two months' duration, without pain or treatment.

Examination showed a papillary ulcer, 3.5 cm. in diameter, on the upper portion of the left side of the vulva with a smaller lesion, 0.5 cm. in diameter, growing below it, together with a well-marked leucoderma of the vulva. The left groin contained a mass of fixed glands, 2.5 cm. in diameter; the right groin was negative.

Pathological report was squamous carcinoma, grade 1.

FIG. 2. Case VIII. N. W. #35796. Fully developed adult type squamous carcinoma, Grade 1.

Treatment began February 23 with an overdosage of radium: 6 gold seeds, each 2.31 mc., 0.3 mm. gold filtration, were buried

Treatment began March 30, with the insertion of 7 gold seeds, a total of 11.03 mc., with a total dosage of 1471 mc.-hrs. On April 5 and

FIG. 3. Case ix. J. G., #35923. Recurrent lesion on admission, March, 1926.

in the large ulcer, a total dosage of 1848 mc.-hrs., one gold seed, 2.31 mc., was placed in the small ulcer, a total of 308 mc.-hrs., three gold seeds, each 2.19 mc., were buried in the mass in the left groin, a total dosage of 876 mc.-hrs.

Treatment caused considerable local reaction with edema of the vulva and fluctuation in the gland mass during the ensuing six weeks. At the end of two months there had been excellent regression of the primary lesion and fibrosis of the glands in the left groin.

On June 1, complete vulvectomy with dissection of both groins was carried out.

CASE IX. *Recurrent carcinoma of the vulva.*

J. G., #35923, married, nullipara, aged forty-five, admitted March 29, 1926.

History of a small, white, painful nodule which appeared on the vulva two years ago and was excised three months later. The lesion recurred in three months and was again excised, August 1925; in November 1925, another quite painful recurrence appeared.

Examination showed a well marked leucoderma of the vulva. The left labium minus had been excised. To the left of the clitoris there was an ulcerated, elevated lesion, 2.5 X 3 cm. in diameter. One hard gland could be felt in each groin.

Pathological report was infiltrating squamous carcinoma, grade II, radioresistant.

FIG. 5. Case x. M. G. H., #38235. Bulky papillary tumor. Superficial ulceration in various places. No infiltration at base. Lesion 4 X 8 X 4 cm.

6, x-radiation was applied to each groin, respectively, 240 ma.-min., 0.5 mm. copper filtration.

There was excellent regression from treatment, but an extensive attack of psoriasis developed, particularly in the lower abdomen.

On June 16, 1926, 2 gold seeds, 3.74 mc., were inserted in the top of the lesion of the left labium, a total dosage of 496 mc.-hrs. Over a year later, July 7, 1927, it was noted that the local lesion was not improving, and on July 23, vulvectomy with dissections of both groins was performed. Up to the present, September, 1929, there is no evidence of recurrence.

CASE X. *Epithelial papilloma of the vulva.*

M. G. H., #38235, single, aged seventy-four, admitted January 7, 1928.

History of a small lump which appeared on the right side of the vulva eleven months previously and gradually increased in size. Pruritus vulvae had been present for ten years; the urine was negative for sugar.

FIG. 4. Case ix. J. G. #35923. Slide from St. Francis' Hospital, from operation on primary growth, August, 1925. Diagnosed by Dr. Ewing as infiltrating squamous carcinoma, grade II+, radioresistant.

FIG. 6. Case x. M. G. H., #38235. Typical epithelial papilloma. Extensive perivascular plasma-cell infiltration.
No definite evidence of carcinoma.

Examination showed the right side of the vulva covered by a bulky, papillary growth, $4 \times 8 \times 4$ cm., slightly ulcerated in places. The tumor did not seem to infiltrate the base. No glands were palpable in the groins.

Diagnosis was epithelial papilloma of the vulva.

Treatment consisted in excision of the tumor mass, January 10, 1928. No radiation was given.

Pathological report was epithelial papilloma; the under border is irregular but shows no definite infiltration; there is an extensive perivascular plasma cell infiltration.

MALIGNANT GROWTHS OF THE EXTERNAL GENITALIA

BENJAMIN S. BARRINGER, Attending Urologist

The control of carcinoma of the bladder at the Memorial Hospital for the past fifteen years has been by means of radium implantation into the growth. No matter how accessible the growth for operative removal, this latter has never been attempted.

In a large majority of cases, implantation is made under vision through the open bladder. The technic consists in opening the bladder under spinal anesthesia, cauterizing off any pedunculated parts of the tumor, and implanting the base with gold seeds, using one seed of 2 mc. to each square centimeter of base. The operative mortality of radium implantation through a cystotomy wound in more than 150 consecutive personal cases has been between 3 and 4 per cent.

With this method of treatment, we have been able to cure cases which were beyond operation, and the percentage of control in both papillary and infiltrated carcinoma is better than that shown by operative statistics.

Prostatic carcinoma has been treated as follows: Intensive deep x-ray therapy from five portals of entry is given to the prostate; in addition, in those cases in which the growth is reasonably small and confined to the prostatic and periprostatic regions, gold seeds are implanted through

the perineum into the carcinoma. These procedures have no effect upon reducing the residual urine, if any be present, but as a rule, they prevent its increase. The problem of residual urine is dealt with by a minor operation by punching out the obstructing portion of the prostate through the urethra.

CASE XI. *Carcinoma of the bladder.*

J. B. H., female, married, aged fifty-three, admitted March 1922.

History of frequent and painful urination of one year's duration, without hematuria.

Examination by cystoscopy revealed on the left side of the bladder vault, running from one to five o'clock, a papillary tumor 3.5 sq. cm. in size, with a surface slough. The growth extended within half a centimeter of the left ureteral orifice.

Pathological report was papillary carcinoma with atypical, hyperchromatic cells.

Treatment consisted of two implantations of glass seeds through the cystoscope, first, with four seeds of 1.08 mc. each in the base, and the second time, with five seeds of 1 mc. each in the base.

The patient has remained well to date, over a period of seven years, and cystoscopically no tumor is present. She has had during the past year a slight leucoplakia at the site of the old tumor, proved by pathological examination.

CASE XII. *Carcinoma of the prostate.*

T. A. S., #39380, aged sixty-seven, admitted November 1928.

History of prostatectomy, three months previously, with a microscopic report of carcinoma.

Examination rectally showed a small, rather irregular and somewhat lumpy prostate bed, and a diagnosis was made of recurrent carcinoma of the sheath of the prostate.

Treatment by insertion of radium needles in the prostate was given twice. On November 13, 1928, two needles of 150 mc. each, screened by steel in each side of the prostate, remained in situ for two hours and were then removed. This treatment was repeated January 24, 1929, with two needles of 44 mc. each for three hours.

Today the patient's prostate and periprostatic region feel absolutely soft, and there is no residual urine.

RECTAL CANCER:

PRINCIPLES AND METHODS OF TREATMENT
AT THE MEMORIAL HOSPITALGEORGE E. BINKLEY, Associate Attending
Surgeon

A routine method of treatment is not employed, due to the fact that several varying factors must be taken into consideration, namely, the condition of the patient, the stage of the disease, the location of the tumor, the degree of malignancy of the mass, and the degree of radiosensitivity of the cancer cells. Consequently, cases are classified and treated in accordance with the above clinical and pathological conditions.

Radiation therapy forms the basis of treatment, but colostomy and radical surgical excision are supplemented in all cases in which surgical interference offers an additional advantage. The various types of radiation therapy now employed consist of external applications of radium and high-voltage roentgen-rays and interstitial applications of gold filtered emanation seeds. The additional 4 gm. element pack for external applications, and the increased filter of the emanation seeds have greatly increased the value of radiation therapy in this disease.

In addition to not advocating any routine treatment for rectal cancer, neither do we advocate any routine dose of radiation therapy; the best results are obtained when each case is considered as an individual problem. The following cases demonstrate that adequate radiation therapy in selected cases is capable of producing "clinical cures." The first case shows that this result may be obtained by external radiation alone, when the cancer is of the most radiosensitive type; the second case, one of a more radioresistant type, responded equally well to interstitial radiation in combination with a small dose of high-voltage roentgen rays.

CASE XIII. *Inoperable carcinoma of the rectum treated by external radiation and colostomy.*

T. H., #36130, male, aged thirty-four, admitted May 1926.

History of rectal trouble of six months' duration with attendant loss of 15 lb. in weight. The patient was in an emaciated condition.

Examination revealed a large, stenosing, fixed cancer of the upper rectum.

Pathological report was ulcerating adenocarcinoma.

Treatment began with pelvic cycles of x-radiation, including four portals, the first, May 5 to May 19; colostomy was performed May 29; exploration of the abdomen revealed many enlarged nodes in the mesocolon. Four other x-ray cycles were completed between the dates of June 23, 1926 and April 12, 1927. The intensity of these treatments was 60 min. exposure, 4 ma. of current, filter 0.5 mm. Cu and 1 mm. Al; 200 k. v.; focal distance 50 cm. In addition, the patient received, on January 11, 1927, 20,000 mc.-hr. of radium at 10 cm. from the skin, posteriorly over the sacrum.

The patient has remained free of recognizable diseases for two and one-half years, and is able to carry on his ordinary occupation.

CASE XIV. *Inoperable carcinoma of the rectum treated by colostomy, interstitial and external radiation.*

R. M., #35859, aged sixty-five, admitted March 1926.

History of rectal trouble for three months. Colostomy has been constructed at another hospital, February 1926, after the condition was considered inoperable.

Examination revealed a large, fixed, stenosing tumor of the upper rectum.

Pathological report was adenoma malignum.

Treatment consisted in the implantation of 25 gold seeds, a total of 4700 mc.-hr., by way of the anal canal, on March 12, 1926; on March 15, 1926, six gold seeds, totalling 2230 mc.-hrs., were implanted into the upper limits of the tumor by way of the colostomy opening. Between March 17 and April 4, a pelvic cycle of four high-voltage x-ray treatments was given.

Examination of this patient in January 1927 failed to reveal any evidence of cancer, and he has remained clinically free of disease to date, more than two and one-half years.

CANCER OF THE BREAST TREATED EXCLUSIVELY BY RADIATION THERAPY

BURTON J. LEE, Attending Surgeon, Breast
Department

The treatment of cancer of the breast is often more difficult than that of cancer in other regions of the body, because of the widespread lymphatic system here encountered.

The radical operation has been standard for forty years, yet the results of radical surgery alone, in many clinics, have proved most disappointing. For this reason it has been a part of our plan of treatment of breast cancer to attempt to control this disease, in some cases, by irradiation alone. Certain patients, especially those suffering from other menacing diseases, or whose ages have contraindicated operation, have offered an opportunity for an exclusive treatment by irradiation.

The following cases are presented to give an idea of the type of these patients and to summarize their treatment:

CASE XV. Primary inoperable carcinoma of the breast treated by radium externally and interstitially in combination with x-rays.

F. M., female, single, aged thirty-eight, admitted January 1929.

History of forcible squeezing of the right breast, June 1928, following which considerable swelling appeared but without ecchymosis. A few weeks before admission the patient first noticed dimpling of the skin over the tumor.

Examination by palpation revealed a mass in the upper middle portion of the right breast, measuring $5 \times 4 \times 2.5$ cm. in diameter, of stony hard consistency, and showing definite skin dimpling over it. Three hard nodes were palpable in the right axilla and there was a questionable node in the right supra-clavicular space. The x-ray film was negative for metastases. The growth was grade c by the Clinical Index of Malignancy.

Treatment consisted first in a cycle of four x-ray treatments over the right breast and its drainage areas, given between January 21 and January 31. The exposures were of 360 ma. min., 0.5 mm. Cu and 1 mm. Al filter, 185 k.v., 50 cm. target-skin distance. On

February 4, 1929, there was a slight diminution in the size of the breast tumor. Between February 25 and April 3, 1929, the right

FIG. 7. Case xvii. O. R., #28004. June 9, 1920. Condition of patient on admission.

breast was directly irradiated by the radium element pack for a total of 54,000 mg.-hrs., distributed in five treatments. On June 10, 1929, a marked regression in the size of the tumor was observed. On August 7, 1929, 14 gold radon seeds, containing a total of 29 mc. of radium emanation with a total dosage of 3867 mc.-hrs., were deposited interstitially throughout the tumor, an amount sufficient to distribute five erythema doses in the substance of the tumor.

On September 9, 1929, the tumor was found to have diminished appreciably in size. There have been little or no skin changes induced by this heavy radiation.

CASE XVI. Primary operable carcinoma of the breast treated by external radium therapy only.

B. M., female, married, aged fifty-five, admitted July, 1929.

History of seven lactations, each of two years' duration. Two weeks prior to admission, the patient had pain in the right breast followed by detection of the mass.

Examination revealed a case of primary multiple foci; in the right breast a tumor measuring 3 cm. in diameter could be palpated in the upper outer quadrant in the position of ten o'clock, while a second smaller tumor, 2 cm. in diameter, was found in the upper inner quadrant in the position of two o'clock. The skin was not fixed; both tumors were freely movable; both nipples were erect. Several small nodes were palpable in the right axilla. Roentgenograms of the lungs

FIG. 8. Case xvii. O. R., #28004. August 1920. Specimen of tumor of right breast. Microscopic diagnosis, carcinoma simplex.

revealed evidence of an old bilateral, apical tuberculosis, but no evidence of metastases.

Treatment consisted in a cycle of six treat-

FIG. 9. Case XVII. O. R., #28004. November 1929. Present condition of patient.

ments by the radium element pack, two each to the right breast mesially, the right breast laterally, and the right axilla, totalling 48,000 mg.-hrs., given between the dates of July 7 and August 2, 1929. The breast proper received a total of 32,000 mg.-hrs.; considering the isodosis curve for the radium element pack, the depth dosages for these two breast tumors were as follows:

(1) 120 per cent of an erythema dose throughout the substance of the first tumor, and (2) 130 per cent throughout the substance of the second tumor.

On August 19, 1929, the primary tumor had regressed to one-third of its previous size, a fact which shows that the growths were quite radiosensitive. A radical amputation of the breast is anticipated, five or six weeks after the last treatment.

CASE XVII. *Primary operable carcinoma of the breast treated by x-radiation. Histological verification of carcinoma.*

O. R., female, married, aged fifty-seven, admitted May, 1920.

History of two small lumps in the upper part of the right breast for two years previous to admission.

Examination showed a mass, 3×5 cm. in diameter, with the skin dimpling over it, in the upper middle segment of the right breast.

There were no definite nodes palpable in the axilla; the chest plate was negative; the general physical examination was negative.

This patient was selected as a test case to determine the efficacy of irradiation in the treatment of a primary operable carcinoma of the breast.

Treatment began May 29 with a cycle of four x-radiations given within a period of ten days, one, each, to the right supraclavicular region, to the right upper anterior chest, to the right lower anterior chest, and to the right axilla. The factors were 35 ma.min., 3 mm. Al filter, 135 k.v. and focal distance 10 inches. By August 4, 1920, there was noticeable diminution in the size of the lesion.

Pathological report from a section removed on August 13, 1920 was carcinoma simplex.

During September and November 1920 and in March, 1921, three other similar cycles of x-radiation using the same factors were given. There has been no further treatment.

At the present time, eight and one-half years later, there is no definite palpable disease. There is a slight thickening throughout the right breast which is believed to have been caused by the x-ray treatments. Marked telangiectasis developed during the past few years, and is at present pronounced.

The patient represents a case of primary operable carcinoma of the breast treated entirely by low-voltage x-rays.

FIXED PRE-CALCULATED IRRADIATION DOSAGE OF INTRA-ORAL EPIDERMOID CARCINOMA

DOUGLAS QUICK, Attending Surgeon,
Head and Neck Department

G. FAILLA, Director of Bio-physical
Laboratories

CASES PRESENTED BY

HAYES E. MARTIN, Assistant Attending
Surgeon

EDITH QUIMBY, Assistant Physicist

For some time past we have made a detailed study of the tissue doses received by the tumor masses in successfully irradiated cases of intra-oral carcinoma. These investigations have led us to believe

that the lethal dose of the average intra-oral squamous carcinoma lies between seven and ten skin erythema doses, if adenopathy.

FIG. 10. Case XVIII. C. B., #40290. Cross-hatched area represents cross section of primary lesion in soft palate.

delivered within a period of about ten to twenty days.

Recently we have reversed the process, and in suitable cases have predetermined upon a certain tissue dose to be delivered into the tumor mass. A combination of applicator doses has then been designed so as to produce this desired dose within the tumor. In the 3 cases here presented, radiation therapy was so prescribed.

CASE XVIII. Carcinoma of the soft palate and anterior tonsillar pillar.

C. B., #40290, male, aged forty-two, admitted July 15, 1929.

History of severe sore throat of six months' duration, with dysphagia and loss of weight.

Examination showed an irregular, deeply ulcerated, sloughing and granular lesion over 4 cm. in its longest diameter, involving the entire soft palate, excepting the uvula, and extending over onto the left anterior tonsillar

pillar and into the groove between the upper and lower alveolar ridges. There was no adenopathy.

Histological report was squamous carcinoma, grade II.

Treatment by x-rays, emanation pack, and gold seeds, with a predetermined tissue dose of 750 per cent SED, was all given within a period of fourteen days.

OUTLINE OF TREATMENT

| Date | Applicator Dose | Tissue Dose (Per Cent SED) |
|---------|--|----------------------------------|
| | X-rays, 165 k.v., 30 cm. target-skin distance 0.5 mm. Cu and 5 cm. oil filter. | |
| 7/17/29 | 150 ma.-min. to left cheek. | 35 |
| 7/19/29 | 150 ma.-min. to right cheek. | 35 |
| | Radium pack at 6 cm. from skin. | |
| 7/25/29 | 16,000 mc.-hr. to left cheek. | 40 |
| to | | |
| 7/28/29 | 16,000 mc.-hr. to right cheek. | 40 |
| | Total from external sources. | 150 |
| 8/ 1/29 | Gold seeds: 25.4 mc. in palate. | 600 |
| | Considered as 4 spheres each 2.25 cm. in diameter. | |
| | Total tissue dose. | 750 |

CASE XIX. Carcinoma of the base of the tongue.

FIG. 11. Case xviii. C. B., #40290. Section taken on admission. Squamous carcinoma, infiltrating adult type, grade II, radioresistant.

T. M., #40726, male, aged forty-nine, admitted July 9, 1929.

History of soreness of the right posterior

of 900 per cent SED, was given by the radium element pack and interstitial gold seeds within a period of nine days.

FIG. 12. Case XIX. T. M., #40726. Cross-hatched area shows location of primary lesion in tongue.

FIG. 14. Case XX. G. E., #40488. Cross-hatched area shows location of primary lesion in tongue.

lateral border, beginning six months ago, and increasing in intensity one month ago.

Examination showed an ulcerated, granular, fissured lesion 3 to 3.5 cm. in its longest diameter, located on the right edge of the tongue opposite the anterior tonsillar pillar, and extending up onto the pillar and the mucosa on the inner side of the alveolar process. The lesion had infiltrated the tongue quite deeply and had excavated the anterior tonsillar pillar. There is no adenopathy.

Histological diagnosis was epidermoid carcinoma, grade II, moderately radiosensitive.

Treatment with a predetermined tissue dose

CASE XX. Carcinoma of the base of the tongue.

G. E., #40488, male, aged sixty-five, admitted May 25, 1929.

History of a sore on the tongue of four months' duration.

Examination showed a flat, indurated lesion of the right base of the tongue extending

OUTLINE OF TREATMENT

| Date | Applicator Dose | Tissue Dose (Per Cent SED) | |
|---------|---|-------------------------------|------|
| | | Primary | Node |
| | X-rays, 165 k.v, 50 cm. target-skin distance 0.5 mm. Cu and 5 cm. oil filter. | | |

forward from the level of the anterior tonsillar pillar, $3.5 \times 2 \times 1.5$ cm. in size. One metastatic node, 1.5 cm. in diameter, was palpable in the right submaxillary region.

Treatment with a predetermined tissue dose of 1,000 per cent SED, was given by x-rays and gold seeds interstitially, within a period of ten days.

SOME TYPES OF RADIORESISTANT TUMORS WITH RESULTS OF TREATMENT

JAMES EWING, Pathologist and Director of Cancer Research

The main object of demonstrating these tumors is to emphasize the following points: first, that the factors entering into radioresistance are very varied; second, that each tumor must be analyzed by itself in accordance with its known structure and clinical behavior; and third, that the results to be attained by radiotherapy in these tumors must be considered in the light of all the factors. Growth restraint is generally all that should be attempted.

CASE XXI. Osteogenic sarcoma devitalized by radiation.

I. D., #31034, female, aged twenty-five, admitted August 29, 1922.

History of an injury to the thigh, nine months earlier, causing severe neuralgic pain which recurred, after disappearing, together with a small lump at the site of the injury. The growth has increased in size in spite of sixteen electric treatments.

Examination showed a large osteogenic sarcoma of the lower end of the femur. It was a typical bone former, and had destroyed the lower 6 inches of the shaft and produced a large swelling of the leg.

Treatment by means of thirteen exposures to high-voltage x-rays, over a period of one year, devitalized the tumor and stopped its growth, but did not reduce its size. Spontaneous fracture occurred two and one-half years after onset, and this event led to amputation. Examination revealed a large central cystic cavity surrounded by a shell of tumor tissue, in which the tumor cells were largely replaced by fibrous tissue. No actively growing portions of tumor could be found. There were no metas-

tases. The patient is well eight years after the onset of the disease.

This case illustrates the devitalization of a highly resistant tumor by prolonged treatment, and it is believed that the radiation was a factor in preventing the usual metastases. Resistance was due to fibrous and osteoid stroma, bulk of tumor, lack of blood vessels, and protection against invading reactive tissues and cells by the capsule.

CASE XXII. Medullary fibrosarcoma. Marked growth restraint and reduction in size of a highly resistant tumor.

B. M., #26304, female, aged thirty-three, admitted March 13, 1919.

History of onset of rheumatic pain in the right knee, one year ago, followed, six months later, by a sudden swelling of the knee. The tumor was excised in January 1919.

Examination revealed a tumor at the lower end of the femur, destroying the shaft, and producing a mass 6 cm. in diameter.

Histological report (1921) was of a markedly fibrous spindle-cell sarcoma.

Treatment, consisting of several series of deep x-ray treatment over a period of three years, caused cessation of growth and reduction in size, but the bone failed to regenerate, and a fibrous mass remained. Amputation was performed in March 1924. The patient has been well for eight years. Resistance was due to the fibrous avascular character of the stroma.

CASE XXIII. Benign bone aneurysm of the lower end of the femur. Devitalization by radiation, but increase in size because of aneurysmal dilatation.

M. G., #30720, female, aged thirty-five, admitted June 13, 1922.

History of a fall and slight cut on the knee, a year previously. Several months later the knee swelled and dull local pain and sharp pain in the foot and ankle have been continuous, in spite of baking and massage. The leg was put up in plaster for eight weeks, until six weeks ago.

Examination showed a tumor of the femur with rather characteristic radiological signs of giant-cell tumor.

Treatment by routine external radiation failed to check the steady increase in size of the growth, which became of very large dimensions, simulating malignant growth. Amputation was performed June 1924, and after this, the

anatomical study revealed a bone aneurysm with free communications with the large arteries together with large cysts filled with fluid and clotted blood, and tumor septa of fibrous nature.

Pathological examination revealed that most of the tumor tissue had been destroyed, while the remainder showed traces of giant-cell structure and calcification.

The patient has remained well for four years. The radioresistance is apparent, not real.

CASE XXIV. *Neurogenic sarcoma, imperfectly treated with radiation without result.*

C. T., #39811, female, aged thirty-three, admitted February 28, 1929.

History of a small swelling near the right elbow, first seen three months ago. Under some form of electrical treatment, the pain and swelling, and disability of the elbow and hand, steadily increased. Two weeks ago, the tumor was surgically removed.

Examination revealed a rapidly growing sarcoma of the upper arm, involving nerve trunks, muscle, and fasciae.

Treatment consisted in the application of 24,000 mc.-hr. of radium at 10 cm. distance, and two high-voltage x-ray treatments. Coley's toxins were administered. As no result appeared in a few weeks, the arm was amputated. There was prompt recurrence in the stump, and the patient died with pulmonary metastases.

Microscopical examination showed a very cellular tumor, with polyhedral type cells, and much resistant fibrous stroma.

The case illustrated a resistant tumor, imperfectly treated, with too brief a time of observation. Genuine radioresistance is not proved in this case.

CASE XXV. *Neurogenic sarcoma, very cellular, but very fibrous and resistant.*

M. P., #39156, female, aged thirty-six, admitted September 18, 1928.

History of a swelling of the thigh, first noticed ten months ago, and operated upon, March 1928, with a diagnosis of spindle-cell fibrosarcoma.

Examination showed a hard, smooth tumor mass, 5 cm. in diameter, deep between the muscles of the thigh.

Treatment amounted to 61,000 mc.-hr. of radium externally, and 40 mc. interstitially. Coley's toxins were given. As there was no definite regression over a period of four months, amputation was done.

Microscopic section showed that the tumor was composed of large spindle cells, very fibrous and very radioresistant.

CASE XXVI. *Liposarcoma of the capsule of the knee joint, resistant after considerable treatment by radium and x-rays. Excision, recurrence and amputation.*

The patient, a female, thirty-five years old, presented a large, firm, lobulated tumor of the knee joint, 12 cm. in diameter. It was treated over a period of six months by x-rays and radium, at moderate intervals. The dosage is not known, but it was not sufficient to affect the skin. There was no regression and the tumor was excised. On section it showed many large polyhedral cells, granular, but containing many fat droplets. The cause of the apparent radioresistance is not apparent, but the dosage seems to have been too small. Other liposarcomas have responded to radiation.

CASE XXVII. *Induced resistance in a diffuse endothelioma of the tibia, after radiation.*

E. V., #28456, male, aged seventeen, admitted December 8, 1920.

History of slow intermittent ache, beginning a year ago, and followed after a few months by a swelling of the tibia. This was incised November 1920, for a supposed osteomyelitis.

Examination showed a fusiform swelling of the upper end of the tibia. Microscopic section (from incision) showed diffuse endothelioma.

Treatment consisted of radium packs, given over a period of one year. Regression was apparently complete. Three years later there was a recurrence of the growth at the upper end of the tumor area and amputation was done.

Section revealed that the main tumor had been rendered highly fibrous and quiescent, but that the fibrous tissue contained many groups of well-stained viable tumor cells. The conditions represent abortive fibrosis. At the upper end of the tibia, where there was no fibrosis, the tumor cells were growing actively.

ROENTGENOLOGIC OBSERVATIONS ON BENIGN TUMORS OF THE STOMACH*

WITH A REPORT OF FIFTEEN CASES

LEO G. RIGLER, M.D.

MINNEAPOLIS, MINN.

BECAUSE of their comparative rarity, non-malignant tumors of the stomach may seem to be a rather academic subject for discussion. Eusterman and Senty¹ estimated some years ago that only 1.3 per cent of all the tumors of the stomach coming to operation were benign. This probably was only an estimate of those tumors which produced symptoms or were accidentally discovered. That they are in reality much more common than this is attested by the fact that the total of reported cases is now approaching a thousand. Eliason and Wright,² for example, report 50 personal cases. Pendergrass³ has seen 30 cases of the pedunculated type alone. During the past two years the author has seen 11 cases in a comparatively moderate number of gastro-intestinal examinations which included some 74 cases of gastric carcinoma.

Hillstrom⁴ in a study of records of the Department of Pathology of the University of Minnesota found that about 5 per cent of all the tumors discovered at post mortem or removed at operation were benign. These figures indicate, therefore, that the condition is not a rare one.

Neither operative or post-mortem statistics, however, present a true picture of the frequency of benign gastric tumors because numerous factors of error are present. They may be unrecognized at operation if the stomach is not opened; they are frequently symptomless; they often become malignant and may not come to operation or post mortem until such carcinomatous degeneration has occurred. There is no doubt that their recognized incidence will increase greatly with the increase in our diagnostic accuracy.

Furthermore, it appears necessary, as in many uncommon conditions, that particular attention be paid to their recognition or they may be frequently overlooked.^{2,5}

The importance of benign gastric tumors is two fold. They may produce symptoms of marked severity, incapacitating the individual who is suffering from this condition. They frequently show malignant degeneration and are very probably the origin of many cases of the polypoid type of gastric carcinoma. Their surgical removal in most cases is comparatively simple and the end-results are so excellent⁶ that their early recognition becomes a matter of the utmost importance.

The literature has been reviewed so well by Eliason and Wright,² Moore,⁵ and Balfour and Henderson⁶ that it need not be further discussed here. These authors discuss the types of tumors and their relative incidence in detail. Only one factor in the etiology stands out. This concerns itself with the close relationship of chronic gastritis and the hypertrophied gastric mucosa to benign polyps and polyposis of the stomach. It seems highly probable that chronic gastritis may develop into polyposis if sufficiently severe. The hypertrophied gastric mucosa resembles a polyp so closely that the clinical or even roentgenological differentiation is very difficult.

Benign tumors of the stomach may be classified pathologically as follows: multiple polyposis, angioma, myoma, fibroma, papilloma, polyp, myoma, fibromyoma, cysts, hypertrophied mucosa, and several other very rare types. From the clinical and roentgenological point of view they are

* From the Department of Roentgenology of the University of Minnesota, the University Hospital and The Minneapolis General Hospital, Minneapolis, Minn. Read before the Hennepin County Medical Society, Oct., 1928.

more simply classified as polypi, ball-valve tumors, angiomata, myomata, and multiple polyposis. The ball-valve tumors

lated tumors especially there may be paroxysmal gastric pain with prostration, vomiting and anorexia. Anemia and weight

FIG. 1. Roentgenogram of stomach and duodenum showing large, central, sharply outlined defect in duodenal bulb. Note thin rim of barium surrounding tumor defect. Defect was due to pedunculated gastric polyp which prolapsed through pylorus.

are pedunculated, attached near the pylorus, and tend to prolapse through the pylorus into the duodenum. They often cause obstruction and roentgenologically may simulate a duodenal tumor.

The symptomatology depends, obviously, upon the size, multiplicity, location and character of the tumor, and as to whether or not ulceration is taking place. In general the symptoms are due to hemorrhage, obstruction, ulceration, or disturbance of gastric function. Eliason and Wright give four groups of symptoms: (1) Indefinite gastric disturbances with pain over a long period relieved by frequent feedings. There may be progressive weight loss, anemia, hematemesis or melena. (2) Symptoms of acute gastritis or ulcer with intermittent hemorrhages and weight loss. (3) Palpable mass with the patient feeling heavy lumps, nausea, and other signs of obstruction. (4) In the peduncu-

FIG. 2. Roentgenogram of stomach showing carcinomatous infiltration on greater curvature in middle third and single polyp in prepyloric region near greater curvature. Note irregularity of malignant infiltration and involvement of contour. Defect due to benign polyp is round, central, sharply outlined and entirely distinct from carcinoma.

loss may or may not be present. It is characteristic of this group that complete recovery may take place until the next attack. The latter group of symptoms may occur with the simple type of hypertrophied gastric mucosa which may prolapse through the pylorus just as would a pedunculated tumor.

The physical signs are essentially negative. It is rare that the mass can be palpated and then only in the exogastric type.

The laboratory findings are not at all consistent. Achylia gastrica is frequent, especially in the cases of generalized polyposis. A secondary anemia which occasionally simulates a primary anemia in its blood picture is present. Blood in the gastric contents has been found, and in a few cases tumor tissue.

The differential diagnosis must be made from carcinoma, ulcer, gastritis, pernicious anemia, and functional dyspepsia.

The roentgen examination with the barium meal is by far the best method

of establishing the diagnosis. In the symptomless cases, which are frequent, it is the only feasible method. It is only in

through the gastric walls in the region of the defect (Fig. 5). (3) The gastric walls are flexible in the region of the tumor. (4) The

FIG. 3. Roentgenogram of stomach showing typical ulcer niche on lesser curvature in middle third and benign polyp in prepyloric region near greater curvature. Defect is central, sharply outlined, round. Peristalsis passed unhindered through this area.

FIG. 4. Roentgenogram of stomach showing multiple polyposis. Sponge-like appearance of stomach is well shown. There are numerous rounded defects, one of which is well shown by pressure applied by palprium (lead ring). Note generalized involvement. Peristalsis was present normally.

recent years that benign gastric tumors have been recognized prior to operation or post mortem. Moore,⁵ for example, states that very few cases were diagnosed correctly prior to 1924 at the Mayo Clinic while at present they seldom make an error in this condition. In one series of 50 cases reported² only 6 had been studied roentgenologically and of these only one was correctly diagnosed. With the use of the proper technic very few cases should escape diagnosis and the only error that may be frequent is the confusion with the polypoid types of carcinoma.

The roentgen signs depend upon the size, shape, location and number of the tumors. The principal findings are as follows (1). A filling defect which is usually central, round or oval, sharply outlined, smooth in contour (Fig. 1). (2) Peristalsis passes

defect itself is frequently movable. (5) A pedicle may be demonstrated. (6) The defect may appear in the duodenal bulb if the tumor prolapses through the pylorus (Fig. 1). (7) The lumen of the stomach is not decreased in size (Figs. 5, 6b, 8). (8) Pyloric obstruction with six-hour gastric retention may be present. (9) In cases of polyposis the barium shadow of the stomach may show numerous small defects resembling a sponge (Fig. 4). (10) In cases of hypertrophied gastric mucosa, the defects may appear as ridges of exaggerated type (Fig. 9). (11) The rugae above and around the tumor may be unaffected.

The technic of examination is of the first importance. Overfilling of the stomach with the barium meal must be avoided and a roentgenoscopic examination with only a

few swallows of barium is necessary. This is well illustrated in Figures 6a and 6b, which are from the same case. The typical defects

FIG. 5. Roentgenogram of stomach showing multiple benign tumors, probably polypi, in middle portion of stomach. Note sharply outlined, central, rounded defects with some evidence of rugae still present distal to tumors. Defects are brought out by pressure.

overfilled as shown in Figure 6b. A similar case is shown in Figure 7. Manipulation of the stomach is of great importance, especially to produce pressure. In this way, as shown in Figures 4, 5 and 6a the defects can be much more clearly seen. Furthermore the mobility of the tumor can be thus demonstrated and in the pedunculated type actual displacement through the pylorus can be produced as previously reported by the author.⁷ The examination must be made both in the upright and prone positions. The observation of peristalsis and flexibility of the gastric walls is of great importance.

Roentgenologically, benign tumors must be distinguished from retained food particles, foreign bodies such as hair balls, gastritis and carcinoma. Food particles are more freely movable, not so round or sharply outlined, and can be eliminated by repeated examination. Foreign bodies are usually larger, more mobile, and

FIG. 6. A. Roentgenogram of stomach only slightly filled showing multiple defects characteristic of benign tumors. These are brought out well by pressure, were somewhat moveable roentgenoscopically. B. Same case showing obliteration of defects in barium shadow due to overfilling of stomach.

shown in Figure 6a were completely lost a few minutes later when the stomach was

produce downward sagging of the stomach. Gastritis may be difficult to distinguish

from multiple polyposis and in the severe cases the differentiation is impossible. The multiple defects in gastritis are long

FIG. 7. Roentgenogram of stomach showing multiple polypi in middle third, brought out well by pressure. At operation, palpation of the stomach revealed no tumors but multiple polypi, with malignant degeneration on their surface, were found when stomach was opened. Note sharply outlined rounded defects with contours of stomach undisturbed.

and narrow rather than round in shape. They are tortuous, take on the form of large rugae and are likely to be more widely distributed. Carcinoma is not sharply demarcated, not mobile, does not permit peristalsis to pass through the gastric wall in its region, obliterates the rugae about it, prevents flexibility of the gastric wall, and often produces a reduction in the lumen of the stomach. Carcinoma rarely remains as a central defect but usually involves the contours of the stomach. Carcinomatous degeneration of a benign tumor may not change its roentgenologic appearance although occasionally infiltration of the wall becomes apparent after malignancy supervenes.

It must be borne in mind that benign tumors may be present in association with other pathological conditions, especially carcinoma. A case of this type was reported previously by the author⁸ and another of the same kind is illustrated in

Figure 2. The association of ulcer and benign tumor may also be demonstrated as shown in Figure 3.

We have been able to collect from our own material 13 cases of benign gastric tumors, 2 cases which were clearly multiple polypi but which on microscopic examination showed malignant degeneration on their surface, and 4 cases of chronic gastritis verging on polyposis. Not all of these cases have been proved by operation or autopsy but in every case reported the roentgenologic and clinical findings are so clear that there is little doubt as to the correctness of the diagnosis.

In this group of cases there are only 6 showing a single tumor. Three of these have been proved to be polyps by pathological examination while the other 3 are characteristic. One of these (previously reported) is shown in Figure 1. The large, sharply outlined defect in the duodenal bulb is characteristic of a pedunculated polyp which has prolapsed through the pylorus. In 2 of these cases carcinoma was present elsewhere in the stomach but having no connection with the benign tumor. One of these has been previously reported.⁸ The other is shown in Figure 2. The small, rounded, sharply outlined filling defect, just prepyloric, is typical of a single polyp. On the greater curvature in the middle third a carcinomatous infiltration can be made out. Between it and the polyp the gastric wall was pliable and peristalsis passed through it unhindered. In another case there was associated with a single polyp, but entirely independent of it, a large penetrating ulcer on the lesser curvature. This is illustrated in Figure 3, the polyp again being just prepyloric while the ulcer is in the middle third. This patient also had a carcinoma of the esophagus. The remaining 2 cases were uncomplicated, single polypi.

One case of generalized polyposis was found in this group. The classical appearance of this condition is well illustrated by this case (Fig. 4). Note the spongy appearance of the barium shadow, the numerous rounded filling defects. The clear way in

which one of these is brought out by the application of pressure is well shown. There were 7 cases of multiple tumors

are entirely lost. In this group there were 2 cases in both of which a diagnosis of multiple polypi was made but malignant

FIG. 8. Roentgenogram of stomach showing large central, rounded, sharply outlined defect in cardiac end. Thought to be due to large fibromyoma but not finally proved.

fairly well localized to one portion of the stomach. A typical one of these is illustrated in Figure 5. The tumors resemble polypi also; they are rounded, sharply defined, are well brought out on pressure and seem to be localized to the middle third of the stomach. One of these cases illustrates very well the extreme importance of examining the stomach with only a small amount of barium and with pressure because these small defects can be so easily obliterated by overfilling. Figure 6a represents the stomach with only 1 oz. of the opaque mixture in it, the film being taken with pressure applied by a palparium. Three distinct and characteristic defects are made out. In Figure 6b the same stomach is shown taken at the same sitting except that it is now filled up with the usual 6 oz. of mixture. The defects

FIG. 9. Roentgenogram of stomach showing marked increase in size of rugae representing appearance of chronic gastritis. Region of pylorus suggests hypertrophied gastric mucosa with possibly some prolapse through pylorus indicated by defect in duodenal bulb. Clinical findings were characteristic.

degeneration of their surface was found on pathological examination. In one of these cases (Fig. 7) an experienced gastric surgeon pronounced the stomach negative after careful palpation during a laparotomy. The patient would have been closed up without any resection if it were not for the confidence placed in the roentgen findings. On opening the stomach multiple papillomata were found which on microscopic examination showed carcinomatous changes.

One case, with a very large tumor of the cardiac end of the stomach, the nature of which was never determined, is included in this series. The sharp demarcation, lack of involvement of the contours, central position and rounded character of this defect (Fig. 8) all indicate that it is benign. The clinical findings support this view very strongly. We have been unable to prove our findings in this case.

Four cases which showed markedly hypertrophic gastric rugae complete this series. In several of these there is considerable doubt as to whether the case is one of polyposis or gastritis. One of these, diag-

nosed polyposis, came to post mortem and was found to have markedly hypertrophic rugae but no true polypi. The pathological difference, however, is not definite. One of these cases (Fig. 9) gave the classical group of symptoms described by Eliason, Pendergrass and Wright,⁹ indicating occasional prolapse of a segment of hypertrophic mucous membrane. The marked increase in the shadows of the rugae is well shown in this case. The linear character of these defects tends to distinguish them from polypi.

SUMMARY AND CONCLUSIONS

Nineteen cases are here reported in which benign lesions of the stomach have been roentgenologically diagnosed. These include 13 cases of benign tumors, 2 cases of benign polypi with malignant degeneration, and 4 cases of hypertrophic gastritis verging on polyposis.

Benign tumors of the stomach are more common than is generally realized.

Their recognition is of great importance because of their tendency to become carcinomatous and because their surgical treatment is so favorable.

The roentgen examination is the best, and often the only, means of diagnosis.

Careful study with small quantities of the opaque mixture and with the application of pressure over the stomach will usually reveal the tumors. It is possible to demonstrate the number, situation and character of the tumors and prolapse through the pylorus may also be diagnosed.

Carcinoma and ulcer may be present in the stomach coincidentally.

Chronic hypertrophic gastritis may give an appearance similar to polyposis and frequently is difficult to distinguish from it.

Thanks are due Dr. Walter H. Ude for assistance in the preparation of this paper and for the privilege of reporting the case illustrated in Figure 8.

STEREOROENTGENOMETRY

A METHOD FOR MENSURATION BY MEANS OF THE ROENTGEN RAY*

CLAYTON R. JOHNSON, M.D.

LOS ANGELES, CALIF.

I HAVE previously described an apparatus and a method¹ for mensuration by means of the roentgen ray. It is my purpose to present a new name for the procedure, to describe a new instrument with its mechanical perfections, to give in some detail the technic of its operation, and to summarize the results of its application to some of the problems of diagnosis.

DEFINITION

Stereo-roentgen-ometry: a process for determining the solid dimensions of a radio-opaque object from its stereoscopic roentgenograms.

Stereo-roentgen-ometer: an instrument used in stereoroentgenometry.

BASIC PRINCIPLE

In Figure 1, xy represents a radio-opaque object in space, somewhere between the target r of the x -ray tube, and the film F . When the target is at position A , the shadow of xy will be cast on the film F as $Ax Ay$. When the target is at position B , the shadow of xy will be cast on the film F , as $Bx By$.

Stereoroentgenometry involves the mechanical reproduction of these conditions. As constants, we have the shift of the target AB ; the vertical target film distance AF ; and the double exposed roentgenogram F , upon which is the shadow of the special marker SM , whose relation to the two positions of the target is known. An apparatus is then designed whereby the relative positions of x and y are established in space, and the distance between them measured directly. In practice a film is used for each exposure, then the two roentgenograms are exactly superimposed according to the shadows of SM .

¹ Johnson, C. R. Mensuration and localization by means of the roentgen ray. *Radiology*, June, 1927.

* Read in part before the Section on Obstetrics, Gynecology and Abdominal Surgery at the Eightieth Annual Session of the American Medical Association, Portland, Ore., July 10, 1929.

THE STEREOROENTGENOMETER

The stereoroentgenometer (Figs. 2, 3 and 4) is an instrument for reproducing

FIG. 1. Illustrating basic principle of stereoroentgenometry.

these conditions. A view box establishes the plane of the roentgenograms and provides illumination. An adjustable bar on the right fixes the roentgenograms in proper position and corresponds to the shadow SM (Fig. 1) of the special marker. Flexible wires, with automatically adjustable length and tension and means of terminal fixation, arise from points similar to the two positions of the target and represent the x -rays. Adjustable pointers fix in space the relative positions of the various unknown points. A special marker (Fig. 5) adapted to the tray of the Bucky diaphragm, casts a shadow upon the margin of the roentgenograms, which is of assistance in their exact superimposition and in the establishment of

their position on the view box. A metal cross marker of known dimensions is used for a check on the accuracy of the technic.

its application to other forms of measurement, especially pelvimetry. Although the author's stereoroentgenometer was de-

FIG. 2. The Stereoroentgenometer. Tips of compass rest upon points marked on promontory of sacrum.

FIG. 3. Tips of compass resting on similar points on shadows of upper border of symphysis.

APPLICATION OF STEREOROENTGENOMETRY

Stereoroentgenometry is applicable to all those conditions wherein the knowledge of solid dimensions may be of value in diagnosis.

The principle is not a new one. Stereoroentgenograms are made use of in many of the various methods for foreign body localization. Chamberlain and Newell¹ have perhaps been most successful in calculating pelvic measurements from stereoroentgenograms. Their method is largely a mathematical one. In 1898, Sir James Mackenzie Davidson described a "cross thread method" for localization of foreign bodies. Again in his book² published in 1916 he reviewed his work and suggested

¹ Chamberlain, W. E., and Newell, R. R. Pelvimetry by means of the roentgen ray. *J. Roentgenol.*, 8: 272, 1921.

² Davidson, Sir J. Localization by X-Rays and Stereoscropy, N. Y., Hoeber, 1916.

veloped entirely independently from any knowledge of the work of Mackenzie Davidson, the instrument bears a family resemblance to the apparatus which he used and recommended so highly.

GENERAL ROENTGENOGRAPHIC TECHNIC

The Potter-Bucky table with tube stand attached is ideal for this work. When once a standard setting is established it can readily be duplicated.

1. Center the target of the tube over the center of the Bucky tray, with a target-film distance of exactly 25 inches.

2. Set the stereoscopic shift for $1\frac{1}{4}$ inches each side of the center, or a total shift of $2\frac{1}{2}$ inches. Use a longitudinal shift.

3. Place special marker in Bucky tray in appropriate notch (Fig. 5). For a 14×17 inch film the inner edge of the marker is

exactly 6 inches from the center of the Bucky tray. For a 10×12 inch film the inner border of the marker is 4 inches from

stereoscopic roentgenograms of a normal case, made two weeks before term. This is the most favorable time for examination

FIG. 4. Measuring distance between sacral promontory and symphysis.

the center. The marker may also be adjusted for other size of film and cassette.

4. Place the cassette in the center of the tray with its further edge beneath the marker. In this position the marker will project over the edge of the film one inch.

5. With a piece of adhesive fasten the cross marker of known dimensions on the patient in such a position that its shadow will be cast on the film.

6. Make stereoroentgenograms with exposure appropriate to the case. The exposure should be of such a density that the desired landmarks will just be clearly visible. If overexposed there will be some difficulty in seeing through both films when they are superimposed.

STEREOROENTGENOMETRY OF THE FEMALE PELVIS

Figure 6 is a tracing from a pair of

FIG. 5. Showing special marker adapted to tray of Brady Bucky diaphragm. The marker is hinged in notches A and B. Its back edge then rests upon cassette.

since most information can be gained. The points for measurement are marked. At the right of the pelvis is the shadow of the cross-shaped marker of known dimensions. This marker is used on all cases as a check on the accuracy of the technic. Its calculated dimensions, as compared with its actual, should check within a millimeter of accuracy.

In determining the dimensions of the pelvis and the fetal head (Figs. 8, 9 and 10), the diameters of the pelvis as given in the textbooks are ordinarily used. In the inlet I have used two additional measurements, which I have called the right conjugate and left conjugate. These diameters extend from the right and left sacroiliac synchondrosis to the symphysis pubis. They are used as an additional check on the anteroposterior diameter of the inlet. As a matter of interest the angle of the plane of the inlet is also calculated. Its

average is about 40 degrees with the horizontal, the patient being in a supine position.

stoscopic roentgenograms as described under "General Roentgenographic Technic." Have patient breath easily. Deep breathing,

FIG. 6. Tracings from pair of stereoscopic roentgenograms showing points marked for measurement.

TECHNIC OF EXPOSURE FOR PELVIMETRY

1. Center the patient to a line just above an imaginary plane passing thru the anterior superior spines of the ilia.

2. Fasten the cross marker to the skin with adhesive near the right inguinal region.

or an attempt to hold the breath, will cause movement of the fetus.

TECHNIC FOR MARKING ROENTGENOGRAMS AND CALCULATING PELVIC DIMENSIONS

The recognition and the marking of the points on the roentgenograms from which

be taken that these points are at the brim of the pelvis, and not at the border of the greater sciatic foramen.

and superimpose them, such that the inner border of the shadows of the special marker are at all times exactly super-

FIG. 13. Case 43. Justo-major type which developed persistent occiput-posterior position.

FIG. 14. Case 40. Kypho-chondrodystrophic type. See table for diameters.

c. The upper border of the pubic symphysis.

d. Arbitrary points on the brim of the pelvis near the normal anatomical location of the iliopectineal eminence, on both sides.

e. The lower border of the symphysis.

f. The inner border of the inferior surface of the body of the ischium. This will usually be visible as a white line about 1 inch in length. Take a point near the center of this line. Take similar point on opposite ischium.

g. The tip of the sacrum at its articulation with the coccyx.

h. If the fetal head is present, mark the sub-occiput, the occiput, the anterior fontanelle, and the frontal region. If the head has not engaged it will usually lie in such position that the shadow of the head is that of the sagittal plane.

i. Mark the tips of the cross bar of known dimensions.

3. Take the films from the stereoscope

impose and parallel during the marking of the points on the other film.

4. Shift the films, one over the other, in a longitudinal direction, until the shadows of the promontory of the sacrum are exactly superimposed. Perforate both films with a needle at the point previously marked with an ink dot.

5. Superimpose the shadows of the anterior surface of the first sacral segment. This automatically fixes the shift of the points on the brim of the pelvis at the sacroiliac synchondrosis. Perforate both films at the ink dots on the brim of the pelvis at the sacroiliac synchondrosis.

6. Superimpose the shadows of the pelvic brim at points marked on the iliopectineal eminence and perforate.

7. Superimpose the shadows of the upper boarder of the symphysis and perforate at the points marked.

8. Superimpose the shadows of the tip of the sacrum and perforate.

9. Superimpose shadows of the lower border of the symphysis and perforate.

10. Superimpose shadows of the inner

wires cross. This will be the actual location in space of the sacral promontory at the time the roentgenograms were made.

FIG. 15. Case 51. Contracted outlet with breech presentation.

FIG. 16. Case 55. Disproportion due to old fracture. Note moulding of head.

margins of the ischial tuberosities and perforate.

11. Superimpose the shadows of the fetal head and perforate at points marked on sub-occiput, occiput, anterior fontanelle, and frontal region.

12. Superimpose the shadows of the special marker (Fig. 7), punch out the holes at the ends of the shadow of the special marker, and place holes over the pegs of the bar on the right of the view box of the stereoroentgenometer.

13. With a ruler draw lines between the points marked on the sacroiliac synchondrosis; also between the points marked on the inner border of the ischial tuberosities (Fig. 7).

14. Take the compass in the left hand and cross the wires once (Fig. 2). Place the tips of the compass on the points marked on the shadows of the sacral promontory. With the right hand bring the tip of one of the pointers to the point at which the

15. With the left hand place the tips of the compass on the points marked on the upper border of the symphysis (Fig. 3). With the right hand bring the tip of the pointer to the point at which the wires cross. This will establish in space the actual position of the upper border of the symphysis.

16. Take the ruler and measure the distance between the tips of the pointers (Fig. 4). This will be the true conjugate.

In like manner determine the remaining diameters of the pelvis.

17. Place the tips of the compass near the mid points of the lines drawn between the points on the sacroiliac synchondrosis (Fig. 7). The point at which the wires cross will be the level of the posterior edge of the pelvic brim. Fix it with the tip of one of the pointers. Then place the tips of the compass on the upper border of the symphysis. The crossing of the wires will mark the upper border of the symphysis. The angle produced by a line through these

two points, with the horizontal, will be the angle of inclination of the pelvic inlet (Fig. 9).

time the roentgenologist studies a stereoscopic roentgenogram of the pelvis, whether for measurement or not, to

FIG. 17. Case 1. .38 caliber bullet in neck causing pressure symptoms on brachial plexus.

FIG. 18. Case 11. Bullet in left lung.

18. Place the tips of the compass near the mid points of the lines drawn between the ischial tuberosities (Fig. 7). Fix the point of the crossing of the wires with the pointer. Then locate the tip of the sacrum in space. The distance between these two points will be the posterior sagittal diameter (Fig. 9).

19. Determine the diameters of the fetal head from points marked.

20. Check the technic by calculating the diameter of the crossed metal marker.

I have purposely gone into minute detail in the above descriptions. The operation may seem rather formidable but really it should be a very simple procedure for the roentgenologist. In the beginning it may be well to take a dried pelvis and calculate its diameters. It will help in recognition of the anatomical points. The next step should be the calculation of the diameters of the pelvis on a suitable non-pregnant subject. It is well that every

identify the anatomical landmarks. Once the technic is acquired, all the desired diameters of the pelvis can be calculated in a period of ten minutes. The stereoscopic roentgenograms may be taken by the average competent x-ray technician, without assistance from the obstetrician or roentgenologist. The examination is free from any injury, and is not in any way embarrassing to the patient.

REPORT OF 50 SELECTED CASES

In Table 1 is a summary of 50 selected cases in which the diameters of the pelvis were determined. These cases have been selected from those referred by experienced obstetricians in private practice, and from those occurring in the Los Angeles General Hospital.

In this summary the cases are grouped as average normal, small or generally contracted, irregularly contracted, those with congenital dislocation of the hip, those in which a persistent occiput-posterior

position developed, those with contracture due to fracture, and one case in which the disproportion was due to a hydrocephalus.

equals or exceeds the suboccipito-bregmatic diameter of the fetal head plus 2 cm. The sum of the transverse and posterior

FIG. 19. Case III. Bullet in left hip showing crossed marker on skin surface directly over foreign body.

FIG. 20. Case IV. Stone in right kidney mistaken for gallstone.

An attempt has been made to correlate the available clinical data with the roentgenologic and with what happened at labor. I have included the external pelvic measurements as determined clinically. I could not get enough exact data as to internal measurements, or as to measurements of the outlet to warrant their inclusion here. It seems that these diameters, if taken at all, are a judgment based on the length of the palpating fingers and the width of the fist. Then follows in the table the pelvic dimensions as determined roentgenologically. The term "sum," refers to the sum of the transverse and posterior sagittal diameters of the outlet. In those cases with prolonged labor, only those have been included which were definitely due to abnormal resistance in the bony canal.

Cases 1 to 20 are representative of the average normal. It is of interest to note that the antero-posterior diameter of the inlet

sagittal diameters of the outlet equals or exceeds the suboccipito-bregmatic diameter of the head times 2 cm. This proportion can not be stated to be absolute but it does give a fair working basis upon which conclusions may be based as to disproportion between the fetal head and maternal pelvis.

Cases 25 to 33 are representative of the borderline or generally contracted type. Case 31 was somewhat of a surprise in that the cooperation of the patient and the ability of the head to mould proved to be the unknown factors. Even then the period of descent was relatively long as compared with the total period of labor.

Case 32 (Fig. 12) gave opportunity to check the diameters of an unmoulded head following delivery by cesarean section. A few hours before delivery the diameters of the fetal head as determined by stereoroentgenometry were: suboccipito-breg-

matic 9.8 cm., occipito-frontal 11.5 cm. Twelve hours following delivery the diameters of the head as measured directly were, suboccipito-bregmatic 9.8 cm.; occipito-frontal 12 cm.

Cases 34 to 40 represent irregular types of contraction. Case 40 (Fig. 14) is a markedly contracted kypho-chondrodystrophic type.

Cases 41 to 42 have congenital dislocation of the hip without pelvic deformity, none, at least, to the extent of producing dystocia.

Cases 43 to 46 developed persistent occiput-posterior positions. The tendency in all of this group is a relatively or absolutely large pelvis as compared with the size of the fetal head. Case 43 (Fig. 13) is typical of the justo-major type of pelvis. The angle of the inlet in all of these cases compares favorably with the average normal.

Cases 47 to 50 all presented by breech. All of these cases show some abnormality. Cases 47, 48 and 51 (Fig. 15) tend toward the funnel type. Case 49 has an oblique contracture of the inlet. Case 50 has an angle of 23 degrees of the pelvic inlet.

Cases 52 to 55 are representative of deformity due to fracture. This was of medico-legal importance in Cases 52 and 53. In both of these cases we could say with assurance that there was no deformity sufficient to interfere with the birth of a normal-sized fetal head. Case 55 (Fig. 16) had 3 cm. shortening of the right oblique diameter. In spite of this the head engaged and was delivered with instruments. The head was greatly moulded.

Case 56 is one of hydrocephalus. The diameters of the head as calculated were 15 cm. suboccipito-bregmatic, and 16.7 cm. occipito-frontal.

Incidentally there have occurred during the collection of this series one case of anencephaly and several cases of multiple pregnancy.

SUMMARY

Stereoroentgenometry as applied to pelvimetry offers a practical roentgenologic

method for accurate calculation of all the internal diameters of the maternal pelvis as well as the essential diameters of the fetal head. The examination also offers incidental information as to the position and presentation of the fetus as well as positive information as to the presence of a fetal monster or a multiple pregnancy.

STEREOROENTGENOMETRY FOR THE LOCALIZATION OF FOREIGN BODIES

Stereoroentgenometry is readily applicable to the localization of foreign bodies.

Technic

1. Fluoroscope the patient and at a point directly over the foreign body place an indellible skin mark.

2. Fasten, with adhesive, the crossed metal marker of known dimensions to the skin at the point marked.

3. Make stereoscopic roentgenograms as described under "General Technic."

4. Place the stereoroentgenograms in the stereoscope and mark the points from which measurements are to be taken, as described under pelvimetry. Place the roentgenograms on the stereoroentgenometer for measurement.

5. Determine the size of the foreign body. If it should be an undeformed bullet, its caliber will be its diameter in millimeters times four; e.g., a bullet 9.5 mm. in diameter will be a .38 caliber bullet.

6. Determine its depth with relation to the skin surface, as shown by the crossed metal marker.

7. Determine its location with relation to surrounding anatomical landmarks.

The following representative cases occurring in The Los Angeles General Hospital will be illustrative.

CASE 1. (Fig. 17). X-ray Report: Slightly deformed bullet in the soft tissues of the neck. Its diameter at the base is 9.5 mm. Its location is 1.5 cm. anterior to the tip of the left transverse process of the 7th cervical vertebra.

Operation by Dr. Carl Rand: A somewhat deformed .38 caliber bullet was readily located in the position described.

CASE II (Fig. 18). *X-ray Report*: An odd-shaped bullet in the lower-left thorax. It is 3.5 cm. in length. It lies 7 cm. posterior to the lower border of the 4th rib, 10 cm. anterior to the lower border of the 8th rib, and 3 cm. to the midline of the 6th rib in the midaxillary line. Fluoroscopically it lies just above the level of the diaphragm.

Operation by Dr. H. E. Schiffbauer: A portion of the sixth rib in the axillary region was resected, and the thorax opened. The bullet was found imbedded beneath the visceral pleura of the lower surface of the lung in the approximate location described. Its length was 3.5 cm.

CASE III (Fig. 19). *X-ray Report*: Bullet in left hip. It is 9.5 mm. in diameter at its base. It lies in an excavation in the upper surface of the neck of the femur at a point 2 cm. to the right of the upper and anterior angle of the greater trochanter.

Operation: The surgeon made a one-inch incision at the level of the upper border of the greater trochanter. By blunt dissection and the sense of touch, he then attempted to locate and remove the bullet. After an hour of discouragement he stated that our localization was all wrong; that he had thoroughly explored the area described and had found nothing. We suggested that possibly the bullet had been dislodged from its location during the blind search. The wound was closed. Re-examination the next day revealed the bullet in the soft tissues below the acetabulum.

During the past year we have had many cases for localization of foreign bodies of various description. The results have been uniformly excellent when the following rules were observed.

1. The removal of a foreign body is in many cases a major surgical procedure. A general anesthetic is usually required and wide exposure is necessary.

2. There must be absolute cooperation between the surgeon and roentgenologist. The roentgenologist must first have well in mind the location of the foreign body. He should be present at the operation and

guide the surgeon in his search. When failure is experienced in the removal of a foreign body, that failure cannot be charged to the method of localization.

STEREOROENTGENOMETRY FOR THE DIFFERENTIAL DIAGNOSIS OF KIDNEY AND GALL-BLADDER CALCULI

CASE IV (Fig. 20). A clinical diagnosis of probable gall-bladder disease.

X-ray Report: Cholecystograms show a non-functioning gall bladder. There is an oval-shaped shadow made up of concentric rings near the lower border of the liver and superimposed over the upper pole of the right kidney. This shadow, when localized, is found to lie in the plane of the kidney. Conclusions: pathological gall bladder. Single kidney stone.

It was suggested that this report might be criticized for even considering that the shadow might be due to a stone in the right kidney. However, after removing a gall bladder filled with stones, re-examination revealed the stone in the kidney, unmoved by the operation.

CONCLUSIONS

Stereoroentgenometry is a process for determining the solid dimensions of a radio-opaque object from its stereoscopic roentgenograms.

It is a practical procedure with which every roentgenologist should be familiar. It provides a ready method of measurement which may be applied to all those conditions wherein the knowledge of solid dimensions is an aid to exact diagnosis. A report of a foreign body is not complete without giving its dimensions and its location with relation to surrounding anatomical landmarks. A report of deformity of the female pelvis should include exact dimensions as to the extent of that deformity.

The stereoroentgenometer is the roentgenologist's "measuring stick."

VALUE OF RADIUM IN THE TREATMENT OF MALIGNANT GROWTHS OF THE FACE*

A. JAMES LARKIN, M.D.

CHICAGO, ILL.

PROBABLY the most common malignant lesion of the face is the rodent ulcer or basal-celled carcinoma. This lesion appears most frequently above a line drawn from the corner of the mouth to the tip of the ear. Contrary to the usual principle that a slow growing benign lesion is often most radioresistant, rodent ulcer seems to be pretty generally radio-sensitive. The lesion is often readily diagnosed on account of its slow growth, rolled edges, crusted or depressed central portion, and induration. Lesions less than 3 mm. in thickness yield readily to relatively small doses of unscreened radium, ordinarily in the proportion of 10 to 15 mg. hr. per square centimeter. The treatment is simple and painless (which is acceptable to the patient), ordinarily with excellent cosmetic results though the end result may be achieved only after a period of about six weeks. Recurrences are not uncommon, but a second or even a third carefully planned radium treatment eliminates the lesion in about 80 per cent of the cases.

Squamous-celled, sometimes called prickle-celled, carcinoma of the face differs from basal-celled lesions in that it is less common, begins slightly below the epithelium, grows more rapidly, may ulcerate later, and not infrequently metastasizes. In spite of its more rapid growth, the lesion is ordinarily more radioresistant than the slow growing basal-celled epithelioma. The common sites for this lesion are the lip, the ear, the nose, and not infrequently the eyelid. In ordinary instances the surface application of unscreened radium can not be depended upon for cure except in lesions less than 3 mm. in thickness. Even in these superficial lesions, it is better to employ a dosage of 15 to 20 mg. hr. per square centimeter. Ordinarily it is

necessary to use some form of interstitial radiation in the form of needles or gold radon implants within the mass in addition to 40 to 60 mg. hr. per square centimeter of gamma rays at 0.5 to 1 cm. distance. Lesions not yielding readily to the first or second application should have careful consideration as regards surgical removal. Other mechanical methods besides excision by scalpel are to be considered and may be classified as surgical measures.

Lesions of either the basal or squamous-celled type which have reached some size require heavier dosage in the form of external, contact and interstitial radiation, sufficient for complete elimination. From 100 to 140 mg. hr. or mc. hrs. per cubic centimeter of involved tissue is an average recommendable dose for interstitial treatment, with reinforcement by gamma rays at a distance.

Lesions of the glabrous skin away from the nose, mouth, eye, or ear are easy of access for treatment and yield correspondingly good results. Lesions located on the eyelids or at either canthi may frequently be eliminated with unscreened contact radiation, though the implantation of radon seeds does much to insure satisfactory results. Lesions involving the nose or ears to such an extent that the cartilage is involved require mechanical removal. Superficial lesions not involving the cartilage often yield readily to vigorous surface radium treatment.

The surgical removal of malignancies of the skin can often be accomplished readily. Most failures are due to inadequately wide excision. Too wide an excision results in less desirable cosmetic results. Many of the lesions of the face are so located that surgical excision with proper technic is not possible or is exceedingly difficult.

* Submitted for publication December 18, 1929.

These lesions merit the consideration of radium therapy for their complete elimination. Other measures such as electrocoagulation with curettage are not infrequently used in a satisfactory manner but always there is the risk that the lesion is squamous-celled and that the trauma of curettage may result in recurrence with a remote possibility of earlier dissemination. Roentgen-ray therapy following surgical excision or coagulation and curettage is used with success in some clinics. With this technic much depends upon the experience and skill of the operators.

One might say, in general, that the treatment of skin malignancies of the face, can well be handled with radium. The percentage

of permanent cures is higher in the larger radium clinics than is obtained by any other methods anywhere. Technic, dosage, and results are frequently reported from these various radium centers, so that the availability of the method to the general medical profession is rapidly increasing. While the results obtained from the surgical treatment do not differ greatly from those obtained by radiation, the simplicity of treatment and technic, the painlessness, the absence of operative procedure, and the superior cosmetic results should induce the profession to explore and make use of, to the utmost, the radium treatment of superficial malignancies of the face.

EDITORIALS

SURGICAL BABBITTS

A GROWING ABUSE

AMERICAN is known by his associates. American Surgery is known by the men who visit foreign clinics as representative of surgery in the United States. On the other side of the water they are forming a negative opinion of our value.

This is because it has become a fad for large groups of American physicians to descend, *en masse*, on well-known foreign clinics. These groups are composed not of well-trained men in the various surgical specialties, but of very mediocre general practitioners off on a holiday and sight-seeing.

We say "very mediocre practitioners" with intent. Often they are men not even outstanding in their home communities. They have done no studying since graduation from medical school, they read almost nothing, neither do they do any

research, add to the literature, visit home clinics or take postgraduate courses. They enjoy large practices or have made a fortune in real estate or the market. They yearn for travel, visits to foreign places, the sights offered by the show places of the world.

Enterprising members of the profession of the go-getter type organize clubs, groups, societies, much on the style offered by any well known travel agency, to visit foreign countries and see "all the clinics." Thirty to a hundred medical Babbitts, who have no idea of what it is all about and care less, "sign up" and in a gay mood depart for distant shores.

Early in the game they were well received. They were entertained and lionized. And then, in many instances, the workers in the foreign clinics woke up to actual facts. They discovered their honored

guests were in a mental fog concerning the work at hand, that they did not know the fundamentals involved, and cared not a hoot about the coarse or fine points under discussion. They were there for a good time. The visit to a medical center was just a line in the itinerary. Herdlike they would descend on a place and overrun it, strain their necks to see all, and were mainly interested in taking moving pictures of everything: the operators, the nurses in the "queer" looking uniforms, Bill from the home town, Jack sitting down in the front row, the anesthetist, the fellow in front, the gang in the back, the outside of the building, the corridors—(wait until we get home and spring these on the boys!)—or else write in little books voluminous notes of their adventures with which to regale the folks on their return.

We know of a hospital resident sent abroad a year to study. He relates that one day the "professor" of a well-known and popular foreign clinic was informed that a medical travel club, for the third or fifth consecutive season, would honor the place on the morrow. Sending for the American resident the professor said, "Take these visiting gentlemen to the Lake and see that they have a jolly time. I'm too busy to be bothered with them."

The Lake referred to is a place built along the lines of our own Coney Island.

We would not infer that all visiting groups of physicians and surgeons are the cause of this abuse. Far from it. Headed by nationally and internationally known surgeons such groups are composed, for the most part, of men who "know their stuff" and are eager to add to the sum of their knowledge. The foreign head of a clinic is acquainted with most of these men, and the students they send to him for study, and are glad to welcome them and be their host. This type of travel club is doing no end of good in fostering cordial scientific relations between our country and the countries abroad.

These Babbitts we have in mind do not come from only the small places; the large cities send more than their quota. They are herded into groups by the small-time imitator of the nationally known men, and feel there is glory in quantity. Let these groups devote their time to the Eiffel Tower, the Tower of London, the night clubs of Paris, and the world's famous restaurants. In this way they will give the real surgical workers a chance.

Let us take a hint from well-founded reports that come to us from abroad and put an end to this abuse.

T. S. W.

SURGEONS AND RADIOLOGISTS

DURING the world war the "liaison officer" came to be well known as the individual who served to correlate the activities of different organizations, especially units of different allied armies. The publisher and the editor have long entertained the sentiment that it would be very desirable to have a liaison organ or organization between surgeons and radiologists. The writer, to whom has come the honor of editing this

section on radiology, has, especially during the last ten years, had numerous opportunities for serving as a sort of liaison officer between surgical and radiological groups.

It therefore seems opportune at this time to establish a section on radiology in this journal. Articles of a highly technical nature relating to radiology naturally find their publication in the journals devoted entirely to radiological interests, and it is not intended that the pages of this

section shall be devoted to such. Rather, it is the desire to devote our space to papers and case reports of a practical surgical nature or of special interest to general practitioners of surgery. This section should therefore appeal to the radiologist who derives a large part of his referred work from surgeons and who should seek to understand as fully as possible the surgical application of his radiological findings. It should appeal to the surgeon because of his inevitable interest in, and his dependence upon, the radiological findings.

In the months to come the editor of this section will endeavor to present in these pages not only suitable contributions but also editorials of an intensely practical nature designed to emphasize many valuable points in the radiology of surgery.

JAMES T. CASE.

SOCIETY NOTICES

At the meeting of the American Urological Association held in Seattle last June Mr. Reinhold Wappler was elected an associate member. He is well known throughout the profession in the United States. He was the founder of the Wappler Electric Company and at the present time he is president of the American Cystoscope Makers, Inc.

The American Association for the Study of Goiter will hold its annual meeting in Seattle, Washington, on July 10, 11 and 12 of this year. The headquarters will be at the Olympic Hotel where two days' session will be held and the meeting of the third day will be at Paradise Inn, Mount Rainier. Arrangements for the meeting are in charge of Dr. J. Tate Mason, of Seattle, Vice-president of the Association.

Subscribers to THE AMERICAN JOURNAL OF SURGERY visiting New York City are invited to make the office of the publishers (Paul B. Hoeber, Inc., 76 Fifth Avenue, New York) their headquarters. Mail, packages or bundles may be addressed in our care. Hotel reservations will gladly be made for those advising us in advance; kindly notify us in detail as to requirements and prices. List of operations in New York hospitals on file in our office daily.

ABRAHAM COLLES

[1773-1843]

BIOGRAPHICAL BREVITIES
"Colles' Fracture"

The American Journal of Surgery
N. S. Vol. viii, January, 1930

"COLLES' FRACTURE"

ABRAMHAM COLLES was born in 1773. His early life was uneventful and he did nothing to cause one to forecast a brilliant maturity. He had the usual academic and professional education of his time.

For thirty-two years (1804-36) he was professor at the University of Dublin. He far outshone his colleagues. He comes down to us labelled "the leading Irish surgeon of his day."

It is recorded that he tied the subclavian artery twice. He reported these cases in the *Edinburgh Medical and Surgical Journal* in 1815. This was a giant feat in the days before anesthesia. He was the first surgeon to tie the subclavian artery within the scaleni.

Although no one has been able to verify

the fact, legend tells us Colles was the first man to successfully tie the innominate artery.

He was a fairly profuse writer on anatomical and surgical topics. In 1811 he wrote a treatise on surgical anatomy. Later in life he did a work on surgery. However, his bid to fame rests on his original description of fracture of the carpal end of the radius or "Colles' fracture." He published an account of this in 1814.

To many he is known for his "Practical Observations on the Venereal Disease" (1837), in which he expounded Colles' law, "relating to the supposed immunity which a healthy mother acquires in bearing a syphilitic child."

Colles died at the Biblical age of seventy years, in 1843.

[From Fernelius' *Universa Medicina*, Geneva, 1679.]

BOOKSHELF BROWSING

ON THE ALLEGED PENETRATION OF THE HUMAN URETHRA BY AN AMAZONIAN CATFISH CALLED CANDIRU

WITH A REVIEW OF THE ALLIED HABITS OF OTHER
MEMBERS OF THE FAMILY PYGIDIIDAE*

PART I

E. W. GUDGER, PH.D.

NEW YORK

INTRODUCTION

THROUGHOUT the Amazon valley for more than a hundred years the tale has been widely told of a fish that has the uncanny habit of penetrating the urethra of men and women bathers, particularly if they should pass urine while in the water. This evil habit has been ascribed to various fishes large and small of the catfish family, but it seems not improbable that mixed with these accounts are exploits attributable to a voracious Characinid fish called Piranha.

For many years I have been collecting and filing away accounts of this alleged habit of the candirú.¹ My editorship of

volume III of the *Bibliography of Fishes*¹ and of its continuation card catalogue, has given me opportunity to go still deeper into the literature of this subject.

In the meantime Dr. C. H. Eigenmann, that distinguished student of South American fishes, had already (1918 a and b) brought together a considerable number of these accounts. However, as I have additional ones (and what are believed to be all ever published) together with a number of first-hand accounts, and since from this large amount of data I have been able to work out what is probably the correct explanation of this long alleged phenomenon, it seems worth while to bring all this data together and to set forth the explanation of this most extraordinary phenomenon for presentation to scientists and especially to medical men. The accounts will now be set forth chronologically, and then an analysis will be

¹ An effort has been made to ascertain the origin and meaning of the word *Candirú* (also spelled *Kandiroo*) but to little purpose. C. F. von Martius in his "*Wörter-sammlung Brasilianischer Sprachen*" (Leipzig, 1867) on p. 37 says that it is a Tupi word, and on p. 442 gives *Canderú* as a variant spelling. As will be seen later, the fish also bears (on the Amazon headwaters) the Spanish name *Canero* or *Carnero*: flesheater.

¹ Published 1923 by the American Museum.

* Submitted for publication October 31, 1929.

attempted in the effort to get at the truth.

THE PUBLISHED CANDIRÚ STORIES

The first account comes from Martius who in his preface to Spix and Agassiz's "Selecta Genera" (1829) says:

Concerning another fish which is also dangerous to man, I ought to add some things. The Brazilians call this fish *Candirú*, the Spaniards living in the province of Maynas [Peru] name it *Canero*. By a singular instinct it is incited to enter the excretory openings of the human body when it can get at these parts in those who are bathing in the river. With great violence it forces its way in and desiring to eat the flesh it unfortunately brings danger to human life. These little fishes are strangely attracted by the odor of urine and consequently the dwellers in these parts when about to go into the river Amazon, in whose bays this pest abounds, constrict the prepuce with a string and refrain from urinating. This fish belongs to *Cetopsis*, a genus which we have described, but I do not know whether these pests are the younger individuals of the species described (*C. candirú* and *C. coecutiens*), or whether they are individuals of a third species of smaller fishes endowed also by nature with this cruel instinct.

Martius in the third volume of Spix and Martius' "Reise in Brasilien" (1831) refers to this matter, repeats the account, and adds to it as follows, localizing the phenomenon at Pará.

Not seldom did we hear in Pará also of the dangers which beset those bathing in the river due to a little fish called Candirú. The things told of this sound so unusual that I myself am almost afraid to relate them here. *Cetopsis* is a genus belonging to the Salmons [Characins] . . . A species of this genus, the Candirú of the aborigines, a little fish of the length and thickness of one's finger—whether the younger individuals of one or both of the species described by us (*Cetopsis candirú* or *C. coecutiens*) or of a third and as yet undescribed species, I unfortunately cannot say since my specimens of this last have been lost—has the habit of entering with great impetuosity and rapidity into the external openings of the human body. It thus brings

about a most painful and dangerous accident since it stretches out its fins and cannot be gotten out save with great difficulty. The odor of man's excretions appears to attract the little fish, and the Indians therefore advise that while in bathing none of this excretion be passed and that this particular organ be covered carefully. The Indians who served me as boatmen corroborated their account of this singular habit by relating several instances. However, as we had observed that the belief in the improbable and the exceptional as well as a ridiculous fear of ghosts constituted a peculiar trait in their characters, their accounts did not convince us until through our friend Dr. Lacerda we as eyewitnesses were made cognizant of the truth of the matter.

The above is translated literally, but is at best ambiguous. It would seem to indicate that Dr. Lacerda personally showed to Spix and Martius an actual case of this phenomenon. This seems improbable for had he done so Martius would undoubtedly have described it differently. What seems to me to be the thought involved is that Dr. Lacerda in the course of his medical practice had had such a case and that he had so clearly described it that they understood it as well as if they had been eyewitnesses. At any rate it would seem that Martius gave full credence to the report.

We next hear of the candirú in the writings of Poeppig (1836). In a footnote to a four-page paragraph on the insect plagues of Maynas, Peru, Poeppig says of a plant called *Xagua* used in warding off insects that:

The fresh juice of the *Xagua* is rightfully claimed to be the surest means of killing and getting rid of these two-inch long little fishes which slip into the outer openings of the bodies of careless [unprotected] bathers and bring about the most dreadful accidents. In Maynas as *Canero* and on the Solimoes [Amazon] as *Candirú*, it is known and feared. The attack of such a fish in such a manner is such an extraordinary thing that one can scarcely believe it. Likewise Herr von Martius (Reise, III, 955) admits being very skeptical of this tale, which he had had from the Indians, until

the well-known naturalist and physician of Pará, Dr. Lacerda, had explained its foundation in truth. In Yurimaguas I myself have been an eyewitness of such a case. An Indian woman, after the penetration by a *Canero* into the vagina, suffered such frightful pain and loss of blood that she was given up to die. However, after both internal and external applications of *Xagua*, the little fish was gotten out and the woman came through alive.

The great superstition of the Indians hindered me in collecting this fish. The only *Caneros* I have are the ones collected in numbers in Yurimaguas. The stage of development of these fishes, though scarcely two inches long, is such that they cannot be taken for young individuals. Unfortunately they spoiled in the weak spirits of the country. As far as memory goes the figures of *Cetopsis* (Martius, Pisces, tab. 10 f. 1, 2) do not appear to agree with the *Canero* of Maynas.

It should be noted just here that Poeppig's journey (1827-1832) followed just ten years after that of Spix and Martius (1817-1820), that he frequently refers to them, that he probably knew Dr. Lacerda in Pará, and, such was his standing as a zoologist, that in 1845 he was made professor of zoology in Leipzig.

In the *Annals and Magazine of Natural History* for 1840, and in *Froriep's Notizen* for 1841, is found the following quotations credited from "Schomburgk's mss.:"

While at San Joaquim, on the Rio Breneo [Branco? a tributary of the Rio Negro] I was frequently warned by the inhabitants to be cautious while bathing of a small fish called *Cancliru*, which they said entered the urethra and rectum, chiefly if one while in the water should satisfy nature; that the greatest difficulty attended the extraction of this little fish, which often caused most dangerous inflammation and even death. Although these accounts were given me by persons whom I had no reason to disbelieve, I could not find any one who had been an eye-witness of such an uncommon event, and I began to doubt its possibility . . . The fish was described to me to be about half an inch in length and gregarious.

This is presumably Robert H. Schomburgk, but careful examination of his

"Fishes of British Guiana" brings to light no reference to our fish, although other fishes from the Rio Branco are described. Examination of the works of Richard Schomburgk also give no data.

Our next author for citation is Castelnau (1855) who first correctly gives our ravenous fish a scientific name and standing in the family Pygidiidae. Under the nomenclature of *Trichomycterus pusillus*, he describes a little siluroid fish (full grown specimens of which were 9 cm. (3.6 in.) long as a new species from the rivers Araguay and Amazon. Of its alleged habits he gives the following amazing account which will be discussed later.

This species is, on the part of the fishermen of the Araguay, the object of a most singular prejudice. They claim that it is very dangerous to urinate into the river, because, they allege, this little animal launches itself out of the water and penetrates the urethra by ascending the length of the liquid column.

When Reinhardt (1859) discovered a small, slender catfish provided with retrose gill-cover spines, living in the gill-cavities of a huge silurid of another family, he named it *Stegophilus insidiosus*. From its habits he sought to connect his fish with the candirú. His full account will be given later, but just here reference only to that part relating to the candirú will be made. He says that the story that the candirú penetrates the urethra or rectum of bathers sounds like a fairy tale, but that there are several reliable accounts of its activities from Spix and Martius, from Schomburgk, and from Castelnau. Then he continues:

That these dangerous small fishes should have the special instinct to make their way into the above mentioned openings in the bodies of bathers will not be believed by many; and it is also evident that only very few fishes could gratify the instinct if they had it; but it is less unnatural that a fish with the mode of living of *Stegophilus* should by accident or mistake act thus. Whether it is exactly the same fish which in different regions has gained such a bad reputation is a question that cannot

be decided at the present time; but it is probably in any case a closely related species; and it is very interesting that, if so, even if it is not a *Stegophilus*, it must be one closely related to it.

Günther (1864) speaking of the fishes belonging to the genus *Vandellia* says: "These fishes are accused of entering and ascending the urethra of persons while bathing, causing inflammation and sometimes death. Although this story is repeated by most travellers in the Brazils none of them has ever seen a case confirmatory of it." This statement is repeated for both *Stegophilus* and *Vandellia* by Günther in 1880 with the added allegation that it lacks confirmation for both.

Marcoy (1869) gives a general account of the fishes of the upper Amazon, and of the candirú specifically says this member of the Siluridae is so little known that he proposes to give a figure and some account of its habits. He writes that its length varies from 2 lines ($\frac{1}{6}$ or 0.17 in.) to 6 inches, that it avoids deep waters but abounds along the shores, especially in inhabited¹ regions where "it has frequent opportunities of satisfying its instincts." and speaks of the rounded head and suckorial mouth beset with close-set, sharp, almost microscopic teeth. There is no doubt that his fish is a pygidiid, but his figure is so crude, in fact so unlike his description, as to be worthless. After describing the habits of the larger forms (to be referred to later), he continues:

The smaller of the species, the size of which barely exceeds 2 or 3 lines ($\frac{1}{6}$ to $\frac{1}{4}$ in., 4 to 6 mm.), are dangerous in quite another respect. Gifted with that faculty so remarkable in trout and salmon, by which they are enabled to mount rapid falls, they introduce themselves into the secret parts of bathers, where their extended fins [spines] retain them captive. Hence the whispered advice which the native bestows on the traveller to avoid passing urine into the water of a bath taken in the river. To the horrible sufferings which the introduction of this living needle may occasion, the Ucayali

¹ For present day confirmation of this, see Dr. de Matta (Part II) as well as others cited elsewhere.

doctors know of but one remedy which consists of a *tisane* made with the *genipa* or *buitach* apple, and which, taken very hot, act, they pretend, on the urinary passages, and dissolves the animal which obstructs them.

Another candirú was collected by the Amazonian explorer Gustav Wallis, and was described by his editor, Karl Müller (1870) as follows:

In these as yet little known waters, particularly in the Huallága, our traveller (G. W.) observed a fish which I wish especially to call to the attention of science. There it is called Candirú and it is rightfully held to be as much the scourge of the waters as mosquitoes and ants are on the land. It itself is only a small thing, scarcely three-quarters of a span long, having a siluroid-like body with a broad rounded head on which the two eyes lie tolerably close to each other, while the two breast fins lie close under it spread out like wings . . . It is a formidable plague for bathers, a species of blood-sucker indeed, which with incredible powers of swimming goes to the body and inflicts a cupping-glass-like wound, and when it has succeeded so that it holds itself fast to the body, it spreads out in the wound a bundle of needles whereby as if with barbs it clings so tightly that only by a painful operation can the fish be separated from the body. This bad habit of the fish is the greater and more dangerous when it seeks out most eagerly the most private parts of the body. Such accidents are related which ended in death as the result of the operation [to remove the fish]. I will therefore take care that this fish, which I have before me in spirits, is put into the proper scientific hands and its scientific name determined since it does not now have one.

This was done and it was described and figured by Lütken in 1891 under the name *Acanthopoma annectens*. His figures of the fish and of the head in both dorsal and ventral aspect are reproduced herein as my Figures 1, 2, and 3, that the reader may at this early stage get a clear idea of the general appearance and peculiar head structures of one of these highly specialized pygidiid catfishes. Particular attention is called to Figure 3 wherein are shown the suckorial mouth beset with teeth

and the spinous pads below the corners of the mouth. Further reference to these will be made later.

FIG. 1.

FIG. 2.

FIG. 3.

FIG. 1. Lateral view of *Acanthopoma annectens* showing slender eel-like form and spinose armature of gill covers.

FIG. 2. Dorsal view of head of same fish showing backwardly pointing spines on upper part of gill covers.

FIG. 3. Ventral view of head of *Acanthopoma*. Note sub-terminal mouth with its many teeth and many backwardly pointing spines on lower part of opercle. (Figs. 1-3 after Lütken, 1891.)

Keller (1874) writes interestingly and apparently at first hand of a number of Amazon and Madeira fishes which he figures. He heard of the candirú as a thin, almost transparent, less than a finger-long fish, dangerous because it "penetrates with eel-like nimbleness into the orifices of bathers and causes many fatal accidents, according to the reports of the riverines." He evidently had no first-hand evidence of this alleged habit.

In 1867 Professor Orton descended the Amazon and heard that "Candirú is the name of two eel-like fishes; and it is also applied to three species of *Serrasalmo* [family Characinidae] all dreaded by bathers." Also that: "The natives accuse a slender Siluroid fish (*Vandellia*) of entering the nether openings of individuals while bathing; but I did not meet with one confirmatory case." Here the name and the fish seem to have been separated and fishes of an entirely different family seem to have been confused in habits with the candirú. However, these points will be taken up later and the confusion cleared up.

In 1884, Steinen, the ethnologist, descended the Xingu from its very head-

waters in Matto Grosso to its junction with the lower Amazon. In his book (1886, p. 150) he lists the candirú among the fishes found in the headwaters (about 14° S. Lat.), and later (p. 178) and much further down the Batovy river (about 12° 8' S. Lat.) he definitely refers to the fish as follows:

We were cautious when bathing. Candirús had been found here. One of them was 2 cm. (0.8 in.) long, a transparent little fish with a yellow iris. They like to push into any available body opening. If, as is said to occur often, they slip into the urethra, the situation is very critical because of the hook-like fins that bury themselves in the mucous membrane. If a hot bath does not bring the disturber out, then the only thing left is an operation. The Sertanejo at that time are said not to have known how to perform urethrotomy, and in many cases death resulted from their heroic treatment.¹

This is not entirely clear although the translation is exact. The "operation" referred to is presumably amputation, of which more further on. However, it is clear that Steinen, a trained scientist, believed that a real danger existed.

At a meeting of the Zoological Society of London in 1897, Dr. G. A. Boulenger, Curator of Fishes in the British Museum, exhibited specimens of *Vandellia cirrhosa* C. and V. collected by Dr. J. Bach in the course of an exploration of the Rio Jurua, a tributary flowing from the southwest into the Amazon some distance above Teffé. With these specimens, Dr. Bach, a physician in active practice in La Plata on the Jurua, had communicated certain data concerning the habits of the fish, which Dr. Boulenger summarized as follows:

The "Candyrú" as the fish is called, is much dreaded by the natives of the Jurua district, who, in order to protect themselves, rarely enter the river without covering their

¹ My attention was called to Steinen's book by a reference thereto (presumably written by R. Blanchard, the editor) in *Archives Parasitologie*, 1903. This note contains no other data. Attention is called to it here to say so and to keep the bibliography of the subject straight.

genitalia by means of a sheath formed of a small cocoanut-shell, with a minute perforation to let out urine, maintained in a sort of bag of palm-fibres suspended from a belt of the same material. The fish is attracted by the urine, and when once it has made its way into the urethra, cannot be pulled out again owing to the spines which arm its opercles. The only means of preventing it from reaching the bladder, where it causes inflammation and ultimately death, is to instantly amputate the penis; and at Tres Unidos, Dr. Bach had actually examined a man and three boys with amputated penes as a result of this dreadful accident. Dr. Bach was therefore satisfied that the account given of this extraordinary habit of the "Candyrú" is perfectly trustworthy.¹

In 1877, C. Jobert collected fishes along the Amazon from Pará to Tabatinga, and while on this tour heard much about and obtained specimens of the candirú. However, he seems to have made no use of this data until his attention was recalled to it by Boulenger's note which appeared early in 1898. Jobert then wrote an article (1898) in which he gave his own observations and critically discussed the whole matter. This valuable paper is too long to quote in full, but will nevertheless be studied in considerable detail.

Jobert begins by quoting the scanty literature known to him and especially considers Boulenger's data communicated by Dr. Bach. In short he notes that none of the authors, not even Dr. Bach, had seen the fish *in situ* or had actual unequivocal proof of the penetration. He does not consider the three cases of amputated penes seen by Dr. Bach as necessarily brought about by action of the candirú, but rather by characin fishes, and thinks that the white man was "taken in" by the Indians, although he does not doubt his good faith. However he (Jobert) had not been twenty-four hours in Pará before he had been repeatedly warned against the candirú and urged to follow the custom of the Indians by wearing the constricting ligature. This advice he thought

to be merely an attempt to "take in a tenderfoot," but when this action was insistently urged on him, he came to see that his informants believed that there was danger from the fish. This impression was heightened when he saw his Tapuyos stolidly apply the ligature to their own bodies before going into the water. When he saw how uncomfortable it was to the wearers, he realized that these men had a profound fear of the danger. This realization was heightened by their astonishment and distress at his refusal to so protect himself. He was not attacked, however, and his immunity was ascribed to some secret preparation which he and other whites used. Later on some of the men, emboldened by his immunity, left off the ligature, but Jobert never heard of any accidents.

But for all that he has said, Jobert does think that there is some foundation for these allegations and of this he had actual experience. He adverts to the fact that the Paraenses had warned him against the candirús (using the plural) and he later found that they distinguished two candirús, probably individuals of different ages. They alleged that the smaller was the true candirú, the urino-philous form: and that the other, too large to enter the urethra, was redoubtable for the wounds which it inflicted on the other parts of the bodies of bathers. This the natives called *Candirú de Cavallo*, alleging that it also attacked horses when in the water.

One day Jobert went in bathing in a canal or channel near Pará, where he was warned that candirús abounded. Here he experienced from some small fishes bites, or better scarifications (to be described later), which showed him that there was some foundation for the reports he had heard. Returning to Pará, Jobert related the incident and showed his wounds to a Dr. Castro, a physician of high standing there, and a man much interested in natural history. Dr. Castro assured him that his wounds were made by the fish

¹ The matter of the protective devices made use of will be discussed fully later.

and gave numerous accounts of the alleged penetration of the candirú into the human urethra in the Amazonian region, and added:

I firmly believe in the possibility of such an accident because I have myself extracted from the urethra of a negress a little candirú which had penetrated during micturation while bathing in the river. The patient experienced cruel suffering for since I had to drag the animal out the extraction was difficult, and the mucous membrane was lacerated.

Jobert seems hardly to know what to make of this, but agrees that it can scarcely be dismissed as a figment of the imagination. He says:

We must conclude that there exist in Brazilian waters fishes of small size capable of attacking man, that the hypothesis of a penetration by these objects in a young stage into the urinary organs is agreed on by all the fishermen, that the recital by Dr. Castro and the observations by Dr. Bach on the Rio Jurua tend to make one consider it as established . . . [But] Before coming to a definite conclusion, it is prudent to wait for more exact information.

The distinguished French ichthyologist, Dr. Jacques Pellegrin has described in three papers (1909a, 1909b, and 1911) a curious little Pygidiid (*Vandellia wieneri*), 92 mm. long, collected in 1881 in the Rio Napo at the foot of the Andes under the equator. In his discussion he adverts at length to all the accounts of the activities of the candirú known to him, and while he sets forth no opinion in the matter, it will be easy for the reader to see that his fish might readily be one of the fishes bearing this colloquial name. Pellegrin's account will be given *in extenso* in a later section.

Algot Lange, in a book for popular consumption, gives the following highly colored account (1912) of our fish and its behavior:

I will mention another species, smaller than the *piranha*, yet, although not as ferocious, the cause of much dread and annoyance to the

natives living near the banks of the rivers. In fact, throughout the Amazon this little worm-like creature, called the *kandiroo* is so omnipresent that a bath house of a particular construction is necessary. The *kandiroo* is usually three or four inches long and one sixteenth in thickness. It belongs to the lampreys, and its particular group is the Myxinos or slime fish. Its body is coated with a peculiar mucus. It is dangerous to human beings, because when they are taking a bath in the river it will approach and with a swift powerful movement penetrate one of the natural openings of the body whence it can be removed only by a difficult and dangerous operation.

A small but hard and pointed dorsal fin acts as a barb and prevents the fish from being drawn back. While I was in Remate da Males the local doctor was called upon to remove a *kandiroo* from the urethra of a man. The man subsequently died from the hemorrhage following the operation.

Largely through the danger of the attack from this scourge, though perhaps not entirely, the natives have adopted the method of bathing in use. A plunge into the river is unheard of, and bath-houses are so constructed as to make this unnecessary. A hole about eighteen inches square is cut in the middle of the floor—built immediately above the water—through which the bather, provided with a calabash or gourd of the bread fruit tree [?] dips water up and pours it over himself after he has first examined it carefully. The indigenous Indians, living in the remote parts of the forest, do not use this mode of protection, but cover the vulnerable parts of the body carefully with strips of bark, which render complete immersion less dangerous.

Of the foregoing it seems only necessary to say that the *Kandiroo* is not a lamprey (such not being found in the Amazon), does not belong to the Myxinidae (which are marine fishes), and possesses no dorsal spine. Furthermore it is of interest to note that no other writer on the habits of the candirú records the use of such a bath house, nor has such a bath house been described in the scores of books on the Amazon read by the present writer. Furthermore, Lange says in the preface (p. xi) to another book (1914) that:

"The Amazon region is full of illusory pitfalls. . . . What at first acquaintance appears to be a thoroughly established fact, upon later and closer analysis proves to be a mistake, and *vice versa*." Thus of Remate de Males, which in the extract above quoted would appear to be a locality he says in referring to his first trip: "Then everything was Remate de Males, '*Culmination of Evils*', to my narrower horizon".

To the present writer the whole account quoted seems based on the widespread fear of the piranhas, and this is changed to the candirú story and is highly embroidered to raise a "thrill" in the reader. It is entirely worthless, and is here set forth merely because it has got into the literature, and in order that its utter unreliability may be explicitly shown.

Krause (1911) in speaking of the dangers of bathing in the Rio Uraguana (a tributary of the Tocantins), enumerates piranhas, crocodiles, freshwater rays, "and in the shallow water the candirú fishes, which are all too eager to push into any body opening." Unfortunately, though a trained scientist, he does no more than make this mere mention.

The next Amazonian traveller to be quoted is Woodroffe (1914), who, after speaking of the piranhas which attack bathers, taking bites out of their bodies, adds:

. . . Another terror of the water [is] called "Candirú." This is a small fish sometimes attaining a length of two inches. Just behind the gills it has two barbs, which, when they enter any orifice of the body, open out and act as do the barbs of an arrow, thereby impeding easy withdrawal or expulsion. Although I have never personally seen a case of sickness due to the proclivity of this fish, I do know that in every place which I visited in my travels I have heard of its dangerous character, and am convinced that the river dwellers do speak truthfully when warning one not to be careless of avoiding this danger.

In 1914 Rudolf von Ihering published a fauna of Brazil listing the animals alphabetically in dictionary fashion. Under

the word candirú we learn that this is a scaleless Nematognathous fish, belonging to the family Trichomycteridae, and correctly named *Vandellia cirrhosa*. Further he says that it is "a species native to the Amazon region, correctly accused of introducing itself into the urinary tract of persons micturating when [bathing] in waters inhabited by Candirús." His scientific work having been done in southern Brazil where the fish is not found, his information is plainly second hand, but he is evidently convinced of the truth of the allegation.

We now come to a series of papers on the pygidiid catfishes by the late Dr. C. H. Eigenmann, the outstanding authority on South American fishes. In the first article (1917) he refers in general terms to the evil habits of the candirús. In the second he gives a more extended account, but our main interest is in the last paper (1918b), a great monograph on the Pygidiidae. In this he goes elaborately into the candirú stories and into all the known habits of these fishes as recorded in the literature and as known to him personally. He brings forward no direct evidence bearing on the matter of the candirú (as I shall later) but indicates plainly that he has considerable belief in the oft-told tale. In the matter of the parasitic habits of certain pygidiid fishes, he sets forth certain discoveries of his own which will be presented in a later section. This paper has been of great value to me.

Still later Eigenmann (1922) makes the same general statements in very brief form, and establishes a new genus and species of candirú, *Urinophilus erythrurus*, from which one may judge of his belief in the phenomenon under discussion.

The latest account of the vicious habits of this pest is from the pen of Paul Le Cointe (1922) who is director of the "Musée Commercial de Pará" and a laureat and prize winner of the "Société de Géographie" and of the "Société de Géographie Commerciale." His work on

the Amazon is based on first-hand knowledge from long residence in Amazonia. Of the candirú he says:

Very small, but uniquely occupied in doing evil, is the Candirú (*Cetopsis*), which does not grow longer than 5-8 cm. (2-3.2 inches). It often becomes entangled in the meshes of the net by its hooks and then makes bad wounds by means of the spurs on the angles of its fins. The worst is that it penetrates sometimes into the anal and urinal apertures of men and women bathers and there erects the terrible spines which oppose all efforts to extract it, thus causing terrible disorders if it is not gotten out with the greatest care. I have personally known already three cases of this curious accident.

This is the last of the published accounts which I have been able to find. Certain hearsay information which has come to me in the form of letters from ichthyologists will now be considered. Prof. W. R. Allen, who has made extensive collections of the fishes of the headwaters of the Amazon, writes that:

I was told of numerous cases of the candirú's entering the urethra, but they were always some distance downstream, and when I arrived downstream I was told of many such cases upstream. At Iquitos I got on the trail of some cases and followed as far as there was a clue, or a hope, or a shred of a name to inquire about. The most hopeful of these cases turned out to be a real human being. But alas when I got to his home he had just departed by the last launch.

The Peruvians have a larger fish . . . which they say attacks women. I found the Peruvian men rarely entering the water, the women never. This was more due to the fear of the *carnero* [candirú] than of the *paña* (*piranha* of Brazil).

Mr. W. E. Pearson, another of Professor Eigenmann's students, who has collected fishes from the headwaters of the Amazon, has sent me the following statement which he frankly says is based on hearsay evidence:

An interesting account of the candirú of the Rio Beni region was related to me by a former American citizen who now lives in Bolivia.

At the time the incident happened he was living in a rubber station on the Rio Madidi, an affluent of the middle Rio Beni. His Indian wife was a witness and gave him the following details.

As is the custom among the Indians of South America his wife went with other women to wash clothes in the river. Upon entering the water they removed their garments and sat down Indian fashion to do their washing. They were not at work long when one of their number gave an unearthly shriek of pain, jumped up and ran out on the bank. Her companions ran to her and upon examination found that a "candirú" had entered the external genital orifice and had penetrated some distance into the vagina. She was led to a nearby hut where her companions extracted the fish mechanically. The retrose hooks of the opercular apparatus tore into the flesh causing great pain and considerable loss of blood. The crude method of extraction seemed to cause no lasting ill effects for the woman was soon about her work.

The habits of the "candirú" are well known along the entire Rio Beni but very few inhabitants were able to give more than hearsay stories about it. None of these stories related to attacks on males. The female is apparently the only one attacked in this region. It is certain that anything but the very young of the candirú (*Urinophilus erythrus*) of the Beni basin would be too large to enter the urethra of a man.

Last of all Mr. G. H. H. Tate of the American Museum tells me that he got news of this fish in 1926 on the Mapiri River (one of the Bolivian tributaries of the Mamore). The fish is said to be about 3 inches long, bluish, slimy, with spines which it erects after entering an orifice. It is said to occasion great loss of blood, and can only be removed after clipping the spines. It is much feared.

THE HABITS OF VARIOUS PYGIDIID CATFISHES AND THEIR BEARING ON THE CANDIRÚ STORIES

In making out a case against the candirú, it will be necessary to marshal the evidence as a lawyer would in court, and in general the habits of these fishes will be analysed

carefully and considered at some length. In this way I shall be able to show a steady and unbroken gradation of habits leading to endoparasitism in certain forms, in those species loosely called candirús. We will begin with the habits fundamental to all catfishes.

Secretive Habits. One of the elementary (basal) habits common to all the catfishes (Nematognathi) is that they are bottom dwellers and hidiers, and as such their general tendency is to get out of sight, to hide under logs, stumps, rocks and banks, or even to burrow in mud or sand. This general tendency is particularly marked in the Pygidiidae, where these insinuating habits are helped along by their eel-like bodies and by their peculiar opercular spines.

In the matter of natural hiding places, Eigenmann states (1918a) that one of these pygidiids, Humboldt's "volcano fish," *Eremophilus* ("El Capitan") has the habit of worming its way into holes in the mud and into the banks of streams and of lakes. And again he says that "On the plains of Bogotá the Indians secured the largest specimens of *Eremophilus* by thrusting their arms into the bottom of holes in the banks of streams."

In addition to seeking natural hiding places, certain pygidiids make their own burrows in the sand. Thus Haseman (as quoted by Eigenmann, 1918b, p. 353) says that in 1907 he collected a *Stegophilus insidiosus* in a sand bar in the Rio San Francisco. More specifically Haseman testifies (1911a) that:

In a creek . . . near Santarem, I collected 400 specimens of Candirús (*Stegophilus*) buried in the sand. They are minute and could be seen by millions in this locality, where the water was too shallow to permit the presence of large fishes of any kind. The fishes belonging to the genus *Vandellia*, as well as other genera of the Pygidiidae, lie buried in sand-bars, and I have often seen them when disturbed rise like a flash and bury themselves again in an instant, leaving small round holes where they reentered the sand.

Eigenmann (1918b) says that Mr. E. B. Williamson wrote him of seeing one species climbing the sides of a waterfall probably by means of its opercular spines and suctorial mouth. Of his own personal experience he writes (1918a and b):

I recall one sultry day sitting in a cool clear brook near Honda, Columbia, leisurely raking my fingers through the sand and pebbles on the bottom. Minute fishes darted out of the sand and into it and under small rocks. I lined a dipnet with cheese-cloth and went for them, dipping up sand, gravel and all. I soon had a good number, 89 to be exact, of a new species of the genus *Pygidium*.

Now if these fishes live their lives largely away from the sun, one would expect them to be comparatively colorless. Thus Keller (1874) records the fact that candirús are small fishes almost transparent in body. Jobert's specimens (1898) taken off the wharf at Pará were "reddish-gray, semi-transparent fishes." Haseman found *Vandellia sanguinea* to be translucent. And finally in Eigenmann's great monograph (1918b), nearly every member of the pygidiid subfamilies Vandellinae and Stegophilinae are noted as being "translucent," "no color marking," or "white." Note will be made of this matter again under endoparasitism.

This common inherent tendency to hide, to creep into a crevice or to burrow in the sand, is the first step leading to an extraordinary and unusual form of parasitism in members of the aforementioned sub-families of the Pygidiidae. The next step is to be found in their food and feeding habits: they are carnivores.

Carnivorous Habits. All the catfishes are carnivorous, flesh and blood are the surest baits for them the world over, and the Pygidiidae are not exceptions. Witness Poeppig (1836) who writes of the *caneros* of Pebas (Peru Orientale) that "it was only necessary to let fall into the water a few drops of blood from a shot bird in order to bring together a swarm of these small and voracious animals." In

fact the word *canero* is a derivative of *carnero*, meaning flesh-eater.

That the candirús of the Ucayali are carnivorous was shown by Marcoy in 1869. His Indian companions taught him how to collect these by a method as simple as it is ingenious. His account is as follows:

This little fish, the object of fear and horror to the natives, possessed considerable interest for us. On our return to Tierra Blanca we desired to study it at our ease, and to fish it there was no necessity for lines, berberis [a poisonous plant], or hook. At breakfast or dinner time we took the shell of a turtle which had been killed by Jeanne for the repast, and furnished with this gory trap, to which still adhered a little flesh, we proceeded to the river, in which we immersed it about six inches. The candirús of all sizes, attracted by the bait, instantly darted at the turtle shell; but hardly were they in its cavity than we suddenly raised it out of the water, and thus made two or three prisoners. If we were too busy that day, or were not in the humour to study our captives, we left them in the shell till the morrow, where, gorging themselves with fresh meat, they would get as fat as gold-fish in a globe. Twelve hours' imprisonment, subject to this régime, sufficed for our candirús to pass from the slenderness of early youth to the majestic rotundity of the paterfamilias. Then we released them from their prison either to dissect or paint them. Occasionally we threw them, all alive and frisky in their bath, to the poultry, which fished them up and swallowed them in less time than it takes to record the fact.

Jobert, after his bloodletting by the candirús at Pará in 1876 [presently to be described] sought to collect some of these fish, and was told by an Indian fish-seller in the market that they could be gotten in the river a few yards away. The bargain struck, the Indian hung below the surface of the water just off the wharf the shell of a freshly killed turtle. After fifteen minutes he gently drew it up with a number of reddish-gray semitransparent fish of a maximum length of 4 cm. (1.6 in.). The color and the manner of their capture showed them to be carnivorous, and that they could abrade the skin was proved by

their pricking his fingers with their opercular spines when Jobert essayed to pick them out of the shell.

Haseman (1911a), in his report on his expedition into South America for the Carnegie Museum of Pittsburg, says that: "Piranhas and candirús soon devour other fishes after they have been hooked . . . A freshly killed animal or an imprisoned large catfish left in the rivers over night are sometimes full of Cetopses and parasitic Pygidiids the next morning."

In connection with these blood-sucking habits, it is interesting to note that Eigenmann (1918b) describes as a new species a *Vandellia sanguinea* from the Madeira River and adds that "Mr. Haseman noted that the specimen was white [translucent?], the alimentary canal straight and gorged with blood": hence its specific name. It is undoubtedly a blood-sucker. It should be noted just here that practically all the members of the sub-families Stegophilinae and Vandellinae are white or transparent (some translucent) in color and all have short straight intestines, things which also point to a diet of flesh or blood.

Last of all the published accounts is Le Cointe's (1922) who writes of the candirús that "united in a legion they like to make common cause with the piranhas in order to despoil a dead body of its flesh and even to devour alive a wounded animal which seeks refuge in a water-course." And in a letter received recently Le Cointe reiterates that: "The candirús, which live occasionally in bands of great numbers, are most voracious, and flock by thousands to the dead bodies of animals thrown in the river, leaving at the end of some hours only the perfectly cleaned skeletons."

In the account personally communicated to me by Mr. Pearson, while this paper was being written, is the following pertinent statement concerning a candirú taken in the Rio Beni basin:

A single specimen of *Urinophilus erythrusus* was captured one evening as I was using fresh

meat to attract fish that might be near the river's edge. The meat was permitted to float down stream a short distance and there was picked up in a seine. The fish had fastened itself into the flesh by means of the retrorse hooks on its operculum.

From these definite carnivorous habits of these little catfishes, in which there has been practically no hint of parasitism, it is not a far cry to carnivorous habits of these and kindred forms beginning with external parasitism and ending with at least semi-internal living, that in the branchial chambers of the host. In the next succeeding sections evidence will be brought forward to establish this.

Ectoparasitic Habits of Pygidiid Catfishes. In the preceding section it has been definitely shown that various members of this family are carnivorous. Herein it will be shown that they go further than this by attacking (attaching themselves to) not only living fishes and mammals but even man himself, in this respect in their smaller way rivalling the fierce attacks of their voracious associates, the piranhas.

The first to make mention of this habit is Marcoy (1869), whose account will now be given. However, it may be said that the fish whose actions he describes might easily be piranhas (Characins) since such are their habits also. However, Marcoy distinctly says that it is a silurid fish (and as he figures a large number of fishes of this order, we must presume that he knew them as such) and he declares that its native name is candirú. Here are his own words:

The larger of these [silurid] fishes, measuring five to six inches in length, make a remorseless war on the calves of the natives who come within their reach: they dart impetuously at the fleshy mass, and rend a portion away before the owner of the calf has time to realize his loss. Never did any disciple of Aesculapius who practised tooth-drawing extract a molar with any greater celerity than these candirús detach the morsel of the living flesh for which they show such a decided liking.

That the next fish (chronologically set out) is a pygidiid there can be no doubt, since it was identified by Lütken (1891) as *Acanthopoma annectens* and this identification still stands. Müller writing from Wallis's notes (1870) says of the candirú of the Huallaga that:

It is a formidable plague for bathers, a species of blood sucker indeed, which with incredible powers of swimming goes to the body and inflicts a cupping-glass-like wound, and when it has succeeded so that it holds itself fast to the body, it spreads out in the wound a bundle of needles whereby as if with barbs it clings so tightly that only by a painful operation can it be separated from the body.

Here we have ectoparasitism definitely established if we are willing to take the word of Wallis coming through Müller. This fish is shown in various aspects in Figures 1, 2 and 3. Study of Figure 3 will show the "cupping-glass" apparatus, the ventral mouth with prickle-like teeth in the upper jaw, and on either side the pads of spines on the lower and inner edges of the opercles, the whole forming a very efficient hold-fast mechanism. It should be noticed that Wallis' description of this bloodletting apparatus is the first ever published.

However, when we come to Jobert's account (1898) we get definite experiential evidence. He had been told in Pará that there were two kinds of candirús; the larger, the *Candirú de Cavallo*, which, too large to enter the urethra, was redoubtable for the wounds it inflicted on the bodies of horses and also of men bathing in the river, and the smaller, urinophilous form alleged to penetrate the genital orifices. Notwithstanding these accounts Jobert one day went in bathing in a channel near Pará, where he had been warned that candirús abounded, and had an experience which we will let him tell in his own words:

I had not been in the water more than five minutes when I felt in the lumbar region, on the abdomen, and on the sides of the chest

some light but rapid strokes of a claw. Seeing the water around me tinged red, I hastened to regain the bank and ascertained that in the

As described above in the section on carnivorous habits, Jobert procured some candirús off the wharf at Pará by the

FIG. 4. Lateral view of *Vandellia cirrhosa*, natural size, showing general characters of pygidiid catfishes. (After Cuvier and Valenciennes, 1846.)

regions where I had perceived the sensation of strokes of a claw the blood was escaping from wounds in the form of parallel scarifications, which might have been made by an instrument so regular were they. These constituted groups of five or six lines each of the

FIG. 5. Ventral view of head of *Vandellia cirrhosa*, showing ventrally placed mouth with 5 teeth in upper jaw, and inward and backward pointing spines on lower part of each operculum. (After Cuvier and Valenciennes.)

length of a centimeter and very close together. I was not able to ascertain their depth but these wounds bled freely throughout their whole length.

His companions evinced considerable satisfaction of the "I told you so" kind, and congratulated him that there were no blood-thirsty piranhas about since had they been present he would not have gotten off so easily. Later when Jobert learned more about the piranhas he realized his fortunate escape. Of the danger of these fishes discussion will be had later.

turtle-shell method. When he tried to scoop the fishes out with his bare hand, they pricked his fingers with their spines. Jobert did not know whether this was the fish that scarified him. However, he reports the facts and says that it was the unanimous opinion that this little fish was the candirú of the legends. He was in doubt as to its classification, realizing the difficulty of separating these small catfishes but concluding that it was nearer Castelnau's fish than Spix and Agassiz'. In 1911 Pellegrin worked over Jobert's collections in the Museum d'Histoire Naturelle in Paris and found these bloodsuckers to be the *Stegophilus insidiosus* of Reinhardt, of which we have heard before and shall hear more a little later.

As to the wounds made, the parallel scarifications and their length precluded the idea of their having been made by biting. These could only have been produced by the spine-like teeth of the mouth or by the erected spines on the opercles when these are widely spread and the gill openings as much distended as possible. Finally Jobert concludes with the statement that there certainly exist in Brazilian waters fishes of small size capable of attacking man and drawing blood.

Study of the mouth parts of *Stegophilus* (Fig. 8) show that these could not have made the parallel scarifications (five or six in number). Pellegrin thinks that the fish which attacked Jobert was a *Vandellia*, and probably *V. wieneri*, whose mouth parts are shown in Figure 10. To this I interpose two objections: first, that of this particular species only one specimen has been taken (high up in the

Andes), and second that as may be seen in Figure 10, it has nine teeth in the upper part of the mouth. On the other hand, *Vandellia cirrhosa* (a lateral view of which is shown in Figure 4) has five teeth in the upper jaw, as may be seen in Figure 5, which would make the sacrifices recorded. Furthermore *V. cirrhosa* is known from many localities on the Amazon and at least as far down as Manaos. However, it is possible that both forms are to be found at Pará.

With regard to external parasitism among the Pygidiidae, our best witness is Haseman, whose remarkable collecting-trip through South America has previously been referred to. One interesting statement (1911a, p. 297) of his is that getting bitten by candirús is one of the dangers besetting the collector of fishes in South America. Again and more explicitly he writes (1911b) that:

Some of the species of the Pygidiidae called "Candirú" attach themselves to any kind of fish or animal, including man. By means of suction, for which their mouths are adapted, they fasten themselves on their victim, and then painlessly cut the skin, and gorge themselves upon its blood. The fishes brought into the market at Manaos often show many wounds inflicted by the Candirús. Below the first fall in the Madeira River it is difficult to take a catfish [these fish lack protective scales] which has not been bitten several times by the Candirús.

Pellegrin has in three papers (1909a, 1909b, and 1911) discussed a curious member of the family Pygidiidae, *Vandellia wieneri*. This little fish (92 mm., 3.6 in. long) was collected in 1881 by Charles Wiener in the Rio Napo under the equator. Pellegrin compares this fish with *V. cirrhosa* C. and *V.* and with Castelnau's *V. plazai*, all three being in the Museum d'Histoire Naturelle in Paris, and finds that all are adapted for a blood-sucking manner of life. However, as will be seen later, his own fish shows the most highly specialized structures fitting it for endoparasitic living.

Next Professor Allen wrote in a personal letter (1926) that:

I have never with my own eyes seen the Candirú attack a human being. And just once have I seen it attacking another fish. In that case it had the head and forward part of the trunk inserted through a perforation of the body wall into the body cavity. . . . One man pointed out to me on his own body a scar that he said was due to an attack of a *carnero*. It was on the abdomen above the inguinal region.

Finally, G. S. Myers (1927) describes a little catfish called *carnero* belonging to the genus *Urinophilus* which when taken was half buried in the abdomen of a large catfish (*Pseudoplatystoma*) caught at Iquitos in Peru. He says definitely that: "It had burrowed directly through the body wall and was distended with blood." Because of this habit he not inappropriately designates it *U. diabolicus*. In the same paper he describes under the name *Haemomaster venezuelae* (the Venezuelan blood-sucker) a little pygidiid taken by Dr. Ternetz on the Orinoco in 1925. Of this he wrote me in 1926: "I have just unpacked a *Vandellia* or *Urinophilus* gorged with blood, which Ternetz said a fisherman gave him on the upper Orinoco, having taken it from a large catfish."

Endoparasitic Pygidiids. From what has been recorded in the preceding sections of this paper with reference to the secretive, carnivorous and ectoparasitic habits of these fishes, culminating in their boring into and going into the abdominal cavity of a dead or live fish, or other animal, the reader is not unprepared for an easy transition to what may properly be designated as endoparasitism in the Pygidiidae.

The first to establish the fact of endoparasitic habits in a fish of this family was Reinhardt (1859). He had been led by the reports of perfectly reliable persons in that part of Minas Geraes, Brazil, which he explored, to believe that a huge catfish called *Sorubim* (*Platystoma*) found in the Rio das Velhas (a tributary of the San Francisco) carried its eggs and

young in its capacious mouth. In fact eyewitnesses told him that they had seen the young fishes fall out *from under the gill covers* when this 6-foot catfish was hauled out of the water. Furthermore Reinhardt knew that other South American siluroids practiced oral gestation, and so he determined to try to clear the matter up. He offered the fishermen of Lagoa Santa, where he was collecting, a reward to bring him a *Sorubim* with young in its gill cavities. This led to the interesting discovery which he described before the Natural History Society of Copenhagen in 1858 as follows:

On February 27, 1852, a fisherman brought me a *Sorubim* in the gills of which he said there should be a little "young one." On examination I indeed found there a young fish, hardly an inch long, which was already dead, although the *Sorubim* still showed faint signs of life. The little fish looked so unlike the big one that I was astonished, and upon finding out that the old fish was a male *Sorubim* with a young one, which looked exactly like the first, but was about three times longer, it became clear to me that these two small fishes could in no wise be what it was claimed they were. On the other hand they recalled to me the picture I carried in my mind of a *Trichomycterus* which I had obtained one year previously from the Rio das Velhas under the name of *Cambeja*, or *Bagre molle*. I naturally concluded that the fisherman in order to get the reward offered, had brought me the young of this *Cambeja* and was passing them off as the young of the *Sorubim*. I complained to his face about this procedure, and though I did not obtain any confession from him, I nevertheless had no doubt that I had been made the victim of a swindle. During the few weeks I still remained in Lagoa Santa before starting on my homeward journey to Europe, nothing happened to induce me to think otherwise.

Upon my return home, as soon as I could get access to the literature, and could make a direct comparison between the supposed young of the *Sorubim* and the *Cambeja*, I at once saw that I had made a mistake in assuming that the latter were the young of the former. In short these so-called young of the *Sorubim* were the little fishes which I have had the

honor of exhibiting to the Society. The whole matter became more involved and enigmatical to me, because it appeared that the fisherman, if he had been really guilty of an intended fraud, had for this purpose made use of a fish which was so rare that I had never found it, although I had collected great numbers of the various small fishes in the waters around Lagoa Santa; in fact a fish which I was forced to conclude to be as difficult to obtain as the real young of the *Sorubim*. In 1854, when I again visited Brazil, the solution of the riddle was one of my especial aims. Soon after I arrived at Lagoa Santa in the latter part of November, I indeed reached the solution much more quickly than I had expected, and in the following manner:

A person from the vicinity of Lagoa Santa, but not the same one, who almost three years before had brought me the first *Stegophilus*, came to the village on a Sunday in the middle of December to attend mass according to the custom of the country. He brought with him on this occasion a *Sorubim*, which before he went to church he sold to a Frenchman who had a shop in the town. When mass was over he returned to get his pay, and watched the shopkeeper cut the fish into pieces. He remarked that when the fish had been pulled out of the water there had been five young in its mouth, of which two had remained inside. The shopkeeper looked and actually found the remaining "young," and was kind enough, as he knew the matter would interest me, to immediately bring them to me and relate the circumstances. At the very first glance at the so-called "young" I saw to my surprise that again *Stegophili* had been brought me as the young of the *Sorubim*.

Reinhardt could not believe that there was any attempt to trick him, for there was a total lack of motive. There could hardly be any collusion between this fisherman and the one of three years previous. These men separately could hardly have conceived the idea of the same little fish as the young of the *Sorubim*. No monetary interest was involved since no pay was asked or given, hence the two men would hardly have taken the trouble to work up such an aimless scheme, nor did any one come later to offer *Sorubim*

young. So he came to the belief that he had been entirely wrong in his suspicions and concludes thus:

fish is a parasite and not a commensal, that its slender form fits it to creep between the gill-lamellae of its host, that

FIG. 6.

FIG. 7.

FIG. 8.

FIG. 6. Lateral view of endoparasitic pygidiid fish *Stegophilus insidiosus*.

FIG. 7. Dorsal aspect of head of *Stegophilus* showing opercular spines.

FIG. 8. Ventral view of head of same fish showing mouth more backwardly placed than in *Acanthopoma* (Fig. 3, Note opercular spines. (Figs. 6-8 after Reinhardt, 1859.)

This little fish in reality passes into and abides in the gill-cavities of the *Sorubim*. Its presence there has through an easily explained misinterpretation on the part of the common people given rise in Minas to the story of the *Sorubim's* care for its young.

Tremendously interested by this discovery, Reinhardt made every effort to get other specimens of the *Sorubim* with the included little fishes, but was unfortunately unsuccessful. He did not realize that this was a case of parasitism, though he raised the questions as to what caused the *Stegophilus* to enter this abode, as to whether it got its food in objects brought in its host's respiration, how frequently and in what numbers it is found in the gill cavities of its host, and finally as to whether it stays with the *Sorubim* exclusively or visits other fishes. In naming this little fish *Stegophilus insidiosus* ("the insidious cover-lover") Reinhardt in a remarkable way vindicates the aim of nomenclature, to make the name accurately describe the named.

Figure 6 herein shows the fish in lateral view, and Figures 7 and 8 portray the head in dorsal and ventral aspects to give the details of the gill-cover spines and the teeth in the upper jaw. That this

FIG. 9. Lateral view of *Vandellia wieneri* showing ventral mouth and spinose gill cover. (After Pellegrin, 1911.)

the spines on its gill-covers enable it to anchor itself there, that the teeth on its upper jaw enable it to abrade the tender tissues of the gills, and that its ventrally placed mouth enables it to suck in the blood, all may be perceived by a study of these figures. To Reinhardt then is due the credit for first (unknowingly) demonstrating endoparasitism in a pygidiid catfish.

Günther, largely on the strength of Reinhardt's discovery, in his British Museum "Catalogue" (1864) established the sub-family "Siluridae Branchicolae" (silurid gill-dwellers) to embrace *Stegophilus* to which there was every reason to credit the habit of living parasitically in the gills of its huge host, and *Vandellia* whose marked and very close similarity of structure led him to conjecture similar habits in it. However, in 1880, he says that "there is no doubt that they live parasitically in the gill-cavity of larger fishes (*Platystoma*), but probably they enter these cavities only for places of safety, without drawing any nourishment from their hosts," certainly a queer statement since it alleges parasitism and then retracts it.

In two papers published in 1909 and in a third in 1911, Pellegrin makes out an impregnable case for endoparasitism in *Vandellia wieneri*. The first paper was merely preliminary but in the second (1909b)¹ he goes carefully into the classi-

¹ The data contained in Pellegrin's second paper (1909b) is added bodily as an appendix to another paper published in 1911; mention is made of it here that my bibliography may be kept straight. The interested reader is referred to whichever paper is most convenient for him.

his views of the use of the mask-like organ with its aperture. In reply he kindly says: "Concerning *Vandellia wieneri*, without speaking categorically I nevertheless believe that the opening situated in the middle of the membrane masking the mouth serves for the sucking of the blood." The restricted opening of the gills would considerably facilitate the sucking fast of the fish to its host, and finally the short straight intestine is admirably fitted for the ingestion and digestion of a rich concentrated food like blood.

The points brought out by Pellegrin make it clear that his fish is a blood-sucking parasite adapted for penetrating between the gills of large fishes, and that it or a near relative was Jobert's assailant. Just here let us recall Müller's statement as far back as 1870 about his blood-sucker (identified by Lütken in 1891 as the pygidiid, *Acanthopoma annectens*) which "inflicts a cupping-glass-like wound, and when it has succeeded so that it holds itself fast to the body, it spreads out in the wound a bundle of needles whereby it clings so tightly that only by a painful operation can the fish be separated from the body." For these structures see the drawing of the under side of the head in Figure 3.

One other species, *Branchoica bertonii*, belonging to the Pygidiidae, has been taken from the gills of a host. Eigenmann (1918a and b) has found two specimens (the only ones known) parasitic on a large characin, *Piaractus brachypomus*, one from Asunción, Paraguay, the other from Puerto Bertoni, Alto Paraná. Each was 24 mm. (1 in.) long. As one can see from Eigenmann's figures of the fish and of the head, reproduced herein as Figures 11, 12 and 13, this fish has a round ventrally placed mouth, very small gill openings, and opercles beset above and below with spines pointing backwardly and inwardly. In the upper jaw is a large patch of backwardly pointing spine-like teeth largest in the center. At each corner

of the mouth are two other patches of needle-shaped teeth which point toward each other. These with the help of the

FIG. 11.

FIG. 12.

FIG. 13.

FIG. 11. Lateral view of *Branchoica bertonii*. Note ventrally placed mouth and patches of opercular spines pointing backwards and upwards, and backwards and downwards.

FIG. 12. Dorsal aspect of head of *Branchoica*. Note dorsal patches of backwardly and upwardly pointing opercular spines.

FIG. 13. Ventral view of head of *Branchoica bertonii*. Note small mouth with backwardly pointing teeth in upper jaw, and with laterally placed spines on upper and lower jaws pointing more or less toward each other. Note also position and pointing of opercular spines. (After Eigenmann, 1918.)

opercular spines form an excellent hold-fast and bloodletting apparatus. We have then under consideration a fish which in structures and habits and habitat is almost identical with Pellegrin's *Vandellia wieneri* and Reinhardt's *Stegophilus insidiosus*. After a careful study of Figures 11, 12 and 13 there can be no doubt that *Branchoica* (the gill dweller) is an endoparasite in the gill chamber of its characin host. The proofs are overwhelming.

The eel-like bodies of these little pygidiid catfishes of the subfamilies *Stegophilinae* and *Vandellinae* (see Figs. 1, 4, 6, 9, and 11) fit them for penetrating between the gill lamellae of their host fishes, their opercles with patches of spines above and below enable them to hitch themselves forward and to hold fast securely within the gills, their ventrally placed mouths beset with teeth aided by their restricted gill openings enable them to stick fast, their jaws beset with teeth enable them to scarify the gill tissues of their hosts, and finally helped by their very small gill openings their stomachs can suck

in the blood set free: all these things proclaim these fishes as endoparasites. Their gill-penetration and blood-sucking habits have undoubtedly grown out of their primal ancestral habit of creeping under objects and into cavities for protection and for animal food.

Summing up the whole situation, Eigenmann (1918b) comes to the conclusion that probably all members of the extensive family Pygidiidae are free lives *except* the "parasitic *Stegophilinae* and the urinophilous *Vandellinae*." Hence the plain inference is that our evil-minded fishes called *candirú*s belong to the latter groups, as will be set out in a brief résumé.

From the facts set forth as to the capture of *Branchioica bertonii* and *Stegophilus insidiosus* together with their peculiar head, gill and mouth structures, it is clear that gill-chamber parasitism is proved for them. The same structures, together with their blood-sucking habits, lead to the belief that the *Vandellias*, particularly *V. cirrhosa*, *sanguinea*, and *wieneri* are also parasites and probably endoparasites. The case is hardly less strong against *Acanthopoma annectens*, since its head and mouth structures almost duplicate those of *Stegophilus*.

My own belief is that further study of the habits and life histories of the members of the two subfamilies named by Eigenmann will show that they are parasitic, and probably endoparasitic fishes. But the insistent question is: Are there any members of the subfamilies to which the name *candirú* applies?

(To Be Concluded)

BOOK REVIEWS

THE PRINCIPLES OF CLINICAL PATHOLOGY IN PRACTICE. By Geoffrey Bourne, M.D. (Lond.), M.R.C.P. and Kenneth Stone, M.D. (Oxon.), M.R.C.P. Oxford Univ. Press, 1929.

The authors have undertaken a meritorious task in making a book which indicates in some detail the laboratory aids useful in the diagnosis of different diseases. They call attention to the need for a publication of this kind, as the textbooks on clinical pathology are devoted chiefly to technic of procedure and those

on general medicine do not elaborate laboratory aids sufficiently. The subject is as extensive as the practice of medicine itself and it has evidently been difficult to decide what to include, and what to omit. There are however, a number of modern and important laboratory aids which have bare mention only. The clinical pathologist would also like to see more attention to biological chemical aids and greater detail in cellular pathology in blood diagnostic aids. Numerous views expressed are evidently personal rather than those generally accepted, and utility should have prompted the voicing of both.

THE FEMALE SEX HORMONE. By Robert T. Frank, A.M., M.D., F.A.C.S. Springfield, Ill., Charles C. Thomas, 1929.

This is a much needed work. There has been so much pseudoscientific mental belly-wash concerning the female sex glands and their secretions that it is a distinct relief and pleasure to read scientific, commonsense paragraphs, amply backed by careful laboratory work by a writer who has carved his name large among the sound men of his calling. To everyone interested in obstetrics, gynecology, surgery, and the sex hormone of the female as related to the wide field of medicine this book becomes a working essential.

One cannot give in outline the book without almost copying it in toto. The researches of Dr. Frank on this subject extend back to 1904 and have been continued to date in several well-known laboratories. The book is divided into two parts: Part I deals with the biology, pharmacology and chemistry of the subject; Part II with clinical investigations based on the female sex hormone blood test. The book is 321 pages long and has 86 illustrations and 36 graphs.

Although even the casual reader will see the text represents the most painstaking and scientific work, yet the book is easily read and one does not have to be a research worker to appreciate it. Any physician will read it with pleasure and profit.

DIE CHIRURGIE. Edited by M. Kirschner and O. Nordmann. Lief. 25. Berl., Urban & Schwarzenberg, 1929.

This part of this monumental system of surgery contains the "Surgery of the Brain" by Dr. Egon Ranzi and the "Surgery of the Vegetative Nervous System" by Dr. F. Bruning and Dr. O. Stahl. The illustrations are beautiful and the bibliography fairly complete even

in the American and English literature. The entire work when complete is on a par with the parts already seen. "Die Chirurgie" by Prof. Dr. M. Kirschner and Prof. Dr. O. Nordmann will be a standard for many years to come.

PRACTICAL LOCAL ANESTHESIA. By Robert Emmett Farr, M.D., F.A.C.S. Ed. 2, revised. Phila., Lea & Febiger, 1929.

Dr. Farr has succeeded in the new edition of his work on "Practical Local Anesthesia" in bringing this subject right up to date. This much discussed topic is covered in a complete and authoritative manner within the scope of a 600 page, well-illustrated volume, which should find a place on the reference shelves of every surgeon.

CANCER. A Practical Resume of the Subject for General Practitioners. By G. Jeanneney. Trans. by John Gibson, M.D., and John H. Watson, M.B., F.R.C.S. Lond., H. K. Lewis, 1929.

This little book on cancer, which has had quite a vogue in France for several years, has now been translated and made available for English reading physicians. It is another plea for the early diagnosis of cancer and for the application of radiation therapy where indicated. Concise and practical, this little book has a definite place in the cancer literature and its perusal will help many general practitioners to answer, in a commonsense way, many of the cancer problems presented to them.

SURGICAL DISEASES OF THE THYROID GLAND. By E. M. Eberts, M.D. with assistance of R. R. Fitzgerald and Philip G. Silver, M.D. Phila., Lea & Febiger, 1929.

According to the foreward of Dr. Archibald: "Here one will find set forth in orderly fashion the knowledge acquired not only, or merely, through the management of many cases, but also through a conscientious study of those cases. . . . The work bears the hallmark of personal experience. And to all this there has been added, as I know, a wide knowledge of the work and opinions of others on both sides of the Atlantic." Within the scope of a duodecimo of 238 pages, Dr. Eberts has attempted to cover the entire subject in fifteen chapters. Necessarily short, the book may be considered a good review or introduction to the subject but it will by no means replace, either in completeness or authoritative presentation, a number of the recent, larger and more detailed books that have appeared both in America and Europe.

DIE ROENTGENDIAGNOSTIK DER INTRATHORAKALEN TUMOREN UND IHRE DIFFERENTIALDIAGNOSE. By Dr. Robert Lenk. Wien, Julius Springer, 1929.

Dr. Lenk's book on "Die Rontgendiagnostik der Intrathorakalen Tumoren und Ihre Differentialdiagnose" is one of the most important additions to roentgen literature in recent years. No German-reading surgeon can afford to be without this book and it is to be hoped that it will be made available to English readers. With remarkable clarity, the author has succeeded in showing the definite help that is to be obtained from the roentgen ray in thoracic cases that so often present almost insurmountable diagnostic problems. The chapter on carcinoma of the lung alone makes this book worthwhile to every surgeon.

COMMON INFECTIONS OF THE FEMALE URETHRA AND CERVIX. By Frank Kidd, M.CH. (Cantab.), F.R.C.S. (Eng.), and Malcolm Simpson, M.B., D.P.H. (Cantab.). With additional Chapters by George T. Western, M.D., and M. S. Mayou, M.S., F.R.C.S. Ed. 2. Oxford Univ. Press, 1929.

The first edition of this worthy book came out in 1924. In bringing out the second edition the authors have not seen cause to alter the original chapters. In their preface they say: "The methods therein described have stood the tests of time and experience, and have become recognized and effective. We have added a chapter describing how to hasten on the time of cure by more intensive treatment, and mentioning certain improvements. . . . We call special attention to the chapter on gonococcal arthritis advocating treatment by early active movements of the joints themselves and condemning splints and plaster."

In the treatment of cervicitis among other measures described is amputation of the cervix. Sturmdorf's excision of the cervical mucosa is not described or mentioned. To our mind this is the only omission of any importance.

The book is well written, above the average in this respect, and should have a wide appeal.

UEBER ORGANHORMONE UND ORGAN THERAPIE. By Geh.-Rat. Prof. Dr. August Bier, Dr. W. Fehlow, Dr. A. Gehrke, Dr. U. Luetkens, and Privat-Doz. Dr. A. Zimmer. München, J. F. Lehmanns, 1929.

Any book sponsored by August Bier is entitled to universal attention and this small volume of 90 pages on organotherapy gives a concise, easily understood resumé of the subject in which German reading physicians will be interested. There are four chapters as follows: Ueber Organhormone und Organtherapie,

Organtherapie der Leber-Gallenwegerkrankungen, Organtherapie bei Nervenkrankheiten and Zur Technik der Tierbluthbehandlung des Morbus Basedow.

DISEASES OF THE CHEST AND THE PRINCIPLES OF PHYSICAL DIAGNOSIS. By George William Norris, M.D., Henry R. M. Landis, M.D., SC.D. With a Chapter on the Transmission of Sounds through the Chest by Charles M. Montgomery, M.D., and a Chapter on the Electrocardiograph in Heart Disease by Edward B. Krumbhaar, PH.D., M.D. Phila., W. B. Saunders, 1929.

Norris and Landis' work has become within twelve years, one of the most used and most quoted books in the library of the American physician. It is of value not only to the internist but also to the general practitioner in whose work physical diagnosis plays such an important rôle. The new edition contains the latest data on all questions within its scope. Not loaded with an extensive bibliography, this book contains footnote references wherever necessary. The editorial judgment of the authors in the matter of omissions is to be as much commended as is the clarity and terseness of the material included. This book of almost a thousand pages, well indexed and well illustrated, is not padded in any way and every word adds to the sum total of the information included within its covers.

GRENZ RAY THERAPY. By Gustav Bucky, M.D. Contributions by Dr. Otto Glasser and Dr. Olga Becker-Mannheimer. Trans. by Walter James Highman, M.D. N. Y., Macmillan, 1929.

So much has been said and written regarding the value, or lack of it, of grenz ray therapy that an authoritative book by the pioneer investigator is welcomed. The physical foundation of grenz ray therapy in this book is written by Dr. Otto Glasser. The balance of this book, covering the historical evolution, principles, anatomic and biologic considerations, the technic, clinical symptoms, dangers and treatment in skin and internal diseases, is written by Dr. Bucky. The book covers the ground thoroughly and provides much food for thought. The author himself says: "I have acceded timidly to the request of the publisher for an exhaustive exposition of grenz ray therapy, for the undertaking seemed premature to me," but thorough use of this book by American physicians will undoubtedly go a long way towards settling the future position of grenz ray therapy.

THE AMERICAN ILLUSTRATED MEDICAL DICTIONARY. By W. A. Newman Dorland, M.D., F.A.C.S. With the collaboration of E. C. L. Miller, M.D. Ed. 15, rev. and enl. Phila., W. B. Saunders, 1929.

The publishers claim that this book has two thousand new words "hundreds of them not defined in any other medical dictionary." The reviewer has not undertaken to check this count but we can say that this edition has withstood a very thorough test and has been found to be the most satisfactory dictionary yet found. The preface states that this edition was revised by Dr. Morris Fishbein with the cooperation of the editorial staff of the American Medical Association. It also states that "In this revision official nomenclatures such as those of the American Chemical Society, the Council on Physical Therapy, the Council on Pharmacy and Chemistry, the Association of Pathologists and Bacteriologists, the American Radiological Association, and similar bodies have been followed." It would seem to be most desirable to have a book where the official nomenclatures of the various specialties are co-related. It is surprising to find in so carefully edited a dictionary that the American Radiological Society is mentioned. Careful investigation reveals no such society and it is supposed that The American Roentgen Ray Society, which some years ago attempted to standardize roentgen nomenclature, is referred to. This book of over 1400 pages is more than a dictionary, it is a veritable encyclopedia with a supplementary posologic and therapeutic table that will probably be one of the most used parts of the book. Illustrations are added where necessary and still there is no padding whatever. Every medical editor will, of course, have this book at his elbow. Every medical author should have it. In fact, as an all round reference work it belongs in the office of every physician.

HANDBUCH DER PRAKTISCHEN CHIRURGIE. Edited by Geh.-Rat. Prof. Dr. C. Garré, H. Küttner, E. Lexer. 6 vols. Vol. i. Chirurgie des Kopfes. Vol. iii. Chirurgie des Bauches. Vol. iv. Chirurgie der Wirbelsäule und des Beckens. Vol. v. Chirurgie der oberen Gliedmassen. Vol. vi. Chirurgie der unteren Gliedmassen. Stuttgart, Ferdinand Enke, 1926-1929.

The sixth revised edition of this classic is received with mixed feelings. It brings back memories of the year 1904 when the second edition was published in English under the editorship of the famous Dr. William T. Bull and as "Bull's Surgery" it became, and promised to remain, an outstanding feature of American surgical literature. The English translation was from the second German edition edited by von Bergman, Bruns and von Miculicz. None of the original editors,

therefore, has survived to see this splendid continuation of their work. The feeling of regret that the American edition was not continued and kept up to date is enhanced by an examination of the revised German edition which, under the editorship of Kuettner and Lexer is maintaining in every way the high standard originally set for it. Volume I of this edition was published in 1926 with a statement in the preface that the publishers hoped to issue the complete work by the end of 1927. Accompanying the volumes now before us is the announcement that Volume II, completing the work, will be published in 1930. The difficulties and delays in issuing cooperative compiled works would seem, therefore, to be equally great in Germany as in this country and probably this is an international failing. The latest volumes issued are volumes III on "Surgery of the Abdomen" and volume VI on "Surgery of the Lower Extremities." The articles in the volume by Koerte of Berlin "Surgery of the Peritoneum," "Abdominal Surgery," and "Pancreas" alone make this volume worthwhile, while the 50 page article on the "Liver" by Garré is an outstanding example of *multum in parvo*. The splendid bibliography at the end of each chapter, always an outstanding feature in this work, has been brought up to date and it is refreshing to see the recognition to American literature therein, a thing not to be said of all German works. Practical surgery with reference to the needs of the active surgeon is the keynote of this work. Long philosophic discussions over pathology and etiology that we are so accustomed to in German works are studiously avoided and for quick reference for an active practitioner we know no better work to recommend. The illustrations are well selected and well executed. The type is legible, the paper good and the binding substantial. If memory serves correctly, the five volume translation in 1924 sold for \$30.00 a set. What a commentary on the times that Volume II alone of the new edition costs 99 marks. But this is no fault of the authors or publishers and the work is well worth the price. In fact, compared to some other German publications it may really be called "cheap." Twenty-five years' acquaintance with this work and a thorough scanning of the new edition, far from dimming his enthusiasm, leaves the reviewer with the feeling that the sixth edition is the best that has yet been

published of one of the most practical systems of surgery he has become acquainted with. If you read German, by all means add this work to your library. Would that some William T. Bull of today could induce some enterprising American publisher to bring out a translation of this edition. That it would be at least as popular as the edition of 1904 there can be no doubt.

CLINICAL OBSTETRICS. By Paul T. Harper, M.D., SC.D., F.A.C.S. Phila., F. A. Davis, 1930.

As a clinical obstetrics or a book that deals with the practical side of obstetrics we recommend Dr. Harper's work to every one doing midwifery. It may not appeal to the specialist or teacher of obstetrics as nothing new is added to the well written text. But to the thousands of physicians who look upon obstetrics as a necessary evil and the drudgery part of their work, and who want a book that will straighten them out and give the answers to the common problems they meet every day, we earnestly advise them to own this volume.

THE BLOOD PICTURE AND ITS CLINICAL SIGNIFICANCE. (Including Tropical Diseases). By Prof. Dr. Victor Schilling. Trans. and Ed. by R. B. H. Gradwohl, M.D. Ed. 7 & 8, St. Louis, C. V. Mosby, 1929.

According to the translator's preface, "The world owes a debt of gratitude to Prof. Schilling for his originality, both as a hematologist and as a clinician. He has been courageous enough to enunciate an almost new and original scheme of interpretation of the blood picture in infection. In my experience, I have found corroboration for all his statements that I have had time to follow up. I feel sure that when the great group of American laboratory investigators and clinicians have had time and opportunity to learn these methods, they will find here a great help in everyday practice." To this statement no exception can be taken. With the publication of this book there is no longer any excuse for faulty technic. The author's ideas are presented with true German thoroughness and the translation has been well done. Study of this work by American laboratory investigators and clinicians will probably lead to a more widespread usage of Schilling's methods which have been found so desirable in Europe. The colored plates, while not as good as they might be, answer their purpose. This work represents a real advance in hematology and makes a distinct contribution to diagnosis.

BOOKS RECEIVED

All books received by The American Journal of Surgery are listed in this column as soon as possible after their receipt and this must be considered as adequate acknowledgment. Books that the Editor considers of special interest to our readers will be reviewed in a later issue.

- AFTER TREATMENT OF OPERATIONS.** A Manual for Practitioners and House Surgeons. By P. Lockhart-Mummery, F.R.C.S. (Eng.), M.B., B.C. (Cantab.). Ed. 5, N. Y., William Wood & Co., 1929.
- CANCER PROCESS.** By J. J. M. Shaw. Edinb., E. & S. Livingstone, 1930.
- CLINICAL EXAMINATION OF THE NERVOUS SYSTEM.** By G. H. Monrad-Krohn, M.D., F.R.C.P. Ed. 4, N. Y., Paul B. Hoeber, Inc., 1929.
- CREED OF A BIOLOGIST.** A Biologic Philosophy of Life. By Aldred Scott Warthin, PH.D., M.D., LL.D. N. Y., Paul B. Hoeber, Inc., 1930.
- DERMATEROSES, OR OCCUPATIONAL AFFECTIONS OF THE SKIN.** By R. Prosser White, M.D., C.M., M.R.C.S. Ed. 3, N. Y., Paul B. Hoeber, Inc., 1929.
- DISEASES OF WOMEN.** Symptoms and Treatment. By Franklin I. Shroyer, M.D. Bost., Richard G. Badger, 1929.
- ELEMENTS OF SURGICAL DIAGNOSIS.** By Sir Alfred Pearce Gould, M.D., M.CH. (Oxon.), F.R.C.S. (Eng.). Ed. 7, N. Y., Paul B. Hoeber, Inc., 1929.
- ESSENTIALS OF MEDICAL ELECTRICITY.** By Elkin P. Cumberbatch, M.A., (Oxon.), D.M.R.E. (Camb.), M.R.C.P. Ed. 6, St. Louis, C. V. Mosby Co., 1929.
- ÉTUDES SUR LES MALADIES FAMILIALES NERVEUSES ET DYSTROPHIQUES.** By O. Crouzon. Paris, Masson et Cie, 1929.
- EXPERT (THE).** By Oscar C. Mueller. Los Angeles, Saturday Night Pub. Co., 1929.
- GASTRIC AND DUODENAL ULCER.** By Arthur F. Hurst, M.D. (Oxon.), F.R.C.P. and Matthew J. Stewart, M.B. (Glasg.), F.R.C.P. with the co-operation in the radiological section of P. J. Briggs, M.A. (Cantab.). N. Y., Oxford Univ. Press, 1929.
- GRAPHIC GUIDE TO ELEMENTARY SURGERY.** By Prof. Th. Naegeli, M.D. Translated by J. Soñowman, M.D., M.R.C.P. N. Y., William Wood & Co., 1929.
- HEMORRHOIDS.** The Injection Treatment and Pruritus Ani. By Lawrence Goldbacher, M.D. Phila., F. A. Davis Co., 1930.
- HISTORY OF HEMOSTASIS.** By Samuel Clark Harvey, M.D. N. Y., Paul B. Hoeber, Inc., 1929.
- LIQUIDE CÉPHALO-RACHIDIEN.** Physiologie et Exploration du Système Ventriculo-Méninge. By Riser, M.D. Paris, Masson et Cie, 1929.
- MASTOIDS, ROENTGENOLOGICALLY CONSIDERED.** By Frederick M. Law, M.D. N. Y. Paul B. Hoeber, Inc., 1929.
- NECK, ROENTGENOLOGICALLY CONSIDERED.** By Percy D. Hay, Jr., M.D. Introduction by Henry K. Pancoast, M.D. N. Y., Paul B. Hoeber, Inc., 1930.
- NERVOUS CHILD.** By Hector Chartles Cameron, M.A., M.D. (Cantab.), F.R.C.P. (Lond.). Ed. 4, N. Y., Oxford Univ. Press, 1929.
- OLD AGE.** The Major Involution. The Physiology and Pathology of the Aging Process. By Aldred Scott Warthin, PH.D., M.D., LL.D. N. Y., Paul B. Hoeber, Inc., 1929.
- OPERATIONSLEHRE: ALLGEMEINE UND SPECIELLE CHIRURGISCHE.** By Martin Kirschner and Alfred Schubert. Berl., Julius Springer, 1927.

A CLINICAL STUDY OF THE ABDOMINAL CAVITY AND PERITONEUM

INTRODUCTION*

THIS book has been written very largely at the instigation of Mr. Paul B. Hoeber and his associates. The encouragement of the publishers has brought to present form, notes which were primarily gathered simply as a postgraduate review of the abdomen.

Who interested in surgery does not, in one manner or another, conduct such a postgraduate study? It is natural, from the time when problems of surgical practice first replace the fixed routines of a medical curriculum, that more and more attention be given to clinical observations. Their value is increasingly recognized and this makes it necessary that the practitioner repeatedly review undergraduate subjects in an attempt to find some basis upon which to interpret and evaluate bedside findings. Every surgeon, by some method of his own, continually gathers, studies, and seeks to correlate essential facts concerning the abdomen. Carefully to investigate one clinical detail after another represents little more than an effort clearly to understand and adequately to meet daily professional problems.

Studying the
Abdomen

While to collect such notes is natural, to prepare them for publication is quite another matter. The magnitude of such a task might well stir the temerity of even a learned anatomist or a seasoned clinician. To search through the fundamental branches of medical science: embryology, anatomy, physiology, chemistry, bacteriology, neurology, physical diagnosis,

Compiling a
Clinical Review

* This introduction is intended for the completed book rather than for this single issue of the Journal. It is here, therefore, disproportionately long, but gives to the reader an understanding of the scope and character of the volume as a whole, as it will appear throughout the year. Any desiring to omit the reading of the introduction should turn to the heading, Section I, The Cavity, p. 6.

I

SUPPLEMENT: A. J. S., n.s. Vol. VIII, No. 1, p. 195

for the particular bearing of these subjects upon a problem at hand, is indeed a pleasure. But to present for the consideration of others any large number of surgical topics, intimately involved as they are with the many basic sciences, obviously exceeds the scope of individual authority. Expertness in the presentation of a single phase implies a degree of inexpertness in the presentation of other equally important phases but those far afield from any one specialty. The surgeon when seeking detail or a high degree of precision will always find it necessary to consult numerous separate sources. The single clinical text has inevitable shortcomings. Such a volume can never be in any sense complete, for surgical literature is too vast and new observations and changes are too frequently made. Taking up, also, a mixture of topics, some clinical and some dealing with basic sciences, it is difficult to find a method for presentation which is entirely satisfactory as to logic and arrangement. These difficulties involved in the preparation of a clinical text are too obvious to necessitate discussion.

Advantages of a
Clinical Text

It is true, however, that the busy practitioner is not always willing to collect his information laboriously and piecemeal. There are times when something of depth would gladly be sacrificed for a greater breadth. The convenience of a single volume broad in scope compensates for certain limitations. The single book touching on many subjects serves as a stimulus, its extensive bibliography acting as a wedge, for an entry into new and broader fields. In addition, the inexpertness which is inherent in such a single volume, both inclusive and comprehensive in character, ensures a certain freshness of viewpoint and an elementary style which might prove of distinct advantage.

Scope of this
Book

The notes which form the basis for the present text were collected as follows: Taking little for granted, the most commonplace terms were looked up, in order to discover their true significance and complete meaning; accepted eponyms were dealt with by going, wherever possible, to the original sources and there reading the exact words of the men signified

in the eponyms (such names as those of McBurney, Winslow, Fowler, Murphy, Trendelenburg, etc. which so commonly appear in reference to signs, anatomic locations, and methods for treatment, may represent either vagaries of thought or surgical matters of accuracy); an extensive review was made of current literature as it describes clinical points of demonstrated value regarding the abdomen. In a word, the effort has been to make this a comprehensive postgraduate review. The objective is a more perfect understanding of what is observed at the bedside and in the operating room. The effort is to gain added clarity and precision in those matters which most commonly demand the attention of the abdominal surgeon. Yet the work extends beyond this primary object of examining individually the problems of everyday surgery and includes a study of the fundamentals of the medical curriculum. Old subjects are taken up from new angles.

The material of the book has been divided into four sections, namely:

- I. The Empty Cavity.
- II. The Enteric Tract.
- III. The Solid Abdominal Organs.
- IV. The Peritoneal Membrane.

These notes, then, deal with both a microscopic and a telescopic range of vision. Upon the one hand, they seek to focus clearly upon details, for it is in the observance of these that success, both in diagnosis and treatment, very largely depends. But upon the other hand they seek to maintain a degree of far-sightedness capable of seeing in the patient an individual, all of whose organs are dependent one upon the other, and of simultaneously observing both local and general reactions. Through visualizing surgical problems within both the microscopic and the telescopic range, an effort is made to gain the advantages of each while avoiding the disadvantages of either.

The need for such postgraduate study will seldom be denied. To open the peritoneal cavity is a relatively simple act. Similarly, abdominal closure is not, as a rule, a difficult

Need for
Postgraduate
Study

procedure. Yet it is a matter far from simple to be certain, after this space has been opened and closed, that in the tense interval of the operation everything has been correctly done to serve the best interests of the patient. Abdominal operations uniformly involve a degree of uncertainty. Even the expert surgeon whose extended experience has repeatedly led him into all regions of the abdomen and has brought him over and over again upon new and unexpected abnormalities, finds this cavity a stimulus to constant study. What surgeon has not seen one intra-abdominal condition mistaken for another; or has failed to encounter pathological changes which were complicated in character involving many structures. The operator is well acquainted with the diversity in the manifestations of the diseases within each single organ; he knows the high incidence of congenital defects, and the wide range of intraperitoneal relationships which must be considered as consistent with the normal. Thus, many operative details cannot be planned in advance but can be settled only during the operation. It is an axiom that the abdominal surgeon must enter the peritoneal cavity "prepared for anything and everything."

Intricacies of
the Peritoneal
Cavity

The abdomen presents to the student a veritable puzzle. The intricacies and complications of the peritoneal cavity seem, at times, to be almost without end. Many factors combine to explain this. Among them might be mentioned the size of the space and the number of the organs contained within; the numerous fusions, mesenteries, ligaments and omenta, by which the organs are attached to the parietes; the involved relations of one organ to another, and of all intra-abdominal organs to viscera in other parts of the body; the complex arrangements of blood vessels, lymphatics and nerves; and last but not least the manner in which the peritoneal membrane stretches over and wraps around the walls of the cavity and the surfaces of the structures within, producing a wide variety of bands, folds and fossae. Functional studies are no less confusing. Terminology regarding the abdomen is of mixed origin, is involved and perplexing;

eponyms abound; and available sources for study clearly indicate that much of present knowledge of this region is still elementary and of an incomplete nature. Realizing these difficulties and fully aware of the costs to his patients of the "trial and error" method of learning solely through experience, the conscientious surgeon will spare no expense in time or effort in his preoperative search for operative aids.

With these facts in mind it would seem that no apologies need be made for further time devoted to additional study of the peritoneal cavity and the problems which it presents. Asserting, then, a profound feeling of inadequacy for the present task and a respect both for the importance of the subject and for the learned character of the professional reader, which the book itself might seem to belie; acknowledging indebtedness to the publishers and to early critics for the courage to attempt the work (an undertaking of such scope that the attempt itself is an invitation to unfavorable judgment); seeking and claiming little personal credit in a book intended largely as a review of the work of others; confidently expectant that, due to the many fields necessarily invaded, readers will make reasonable allowance for certain imperfections or even discrepancies which would not be tolerated in a book more specialized in character; and encouraging all suggestions and criticisms, this book is submitted; and by a favorable reception the effort of its compilation will have been, many times over, repaid, while by a reception which is unfavorable the work, following well-established laws, will quickly pass into that oblivion from which no harm can arise. The high aim has been attained if through this study a single operator can be made to feel more at ease during the performance of a single abdominal operation or if a patient in a single instance may thus receive more expedient and effective treatment.

This Publication

SECTION I

THE CAVITY

The study of any physical object may well begin from the vantage point of distance. A proper perspective proves invaluable. The abdomen, accordingly, is first studied with reference to its interrelationships with other parts of the body. Particular stress is placed upon those structures which pass into or out of the abdominal cavity connecting it with other regions. The interpretation of practical points concerning abdominal diagnosis and treatment depends upon the ability clearly to visualize the abdomen, not only as an independent structure, but also as an integral part of the individual.

The initial section of this review is confined to a consideration of the abdomen as an empty space, that is, as simply a container for the organs upon which the surgeon must operate. To remove all abdominal viscera reduces greatly the complexity of intra-abdominal arrangements and to investigate the empty cavity before attempting an investigation of the contents of the cavity serves to simplify this study to a marked degree. The following boundaries of the cavity are separately dealt with: (a) the roof (or diaphragm); (b) the floor (or pelvis); (c) the walls (anterior, posterior and lateral).

Certain introductory matters must logically be considered. Important among these is a definition of terms. A review of such preliminary data serves to establish the solid groundwork necessary to an adequate understanding of the involved and complicated details which follow. While the initial portions of this review may appear, in part, somewhat elementary, they contain a discussion of many practical clinical topics. The following subjects for example are taken up: operative routes of approach to various abdominal organs; means for exploring the lower abdomen through orifices of the pelvic floor; the significance of alterations in intra-abdominal pressures; the mechanism by which extra-abdominal disorders

produce abdominal signs and symptoms; diaphragmatic hernia; peritoneal drainage; abdominal topography.

DEFINITIONS

The abdomen is the body cavity bounded by the diaphragm above and the pelvis below.¹ This corresponds externally to the region extending downward from approximately the level of the nipples to that of the loins. (See Fig. 1, note A.)

The derivation of the word abdomen is probably from the Latin *abdere*, to hide. For this cavity, or cave, effectively hides the normal organs, while in addition its walls serve to conceal the developing fetus or the growing tumor.

The abdominal cavity is a term synonymous with the word abdomen. Within this cavity are situated all of the abdominal organs, namely:²

1. The greater part of the alimentary canal, viz. stomach, small intestine, large intestine.
2. Digestive glands: liver and pancreas.
3. Ductless glands: spleen and two suprarenal glands.
4. Urinary apparatus: the kidneys, ureters, part of bladder.
5. The peritoneum.
6. Blood vessels, lymph vessels, lymph glands.
7. The abdominal portions of the cerebrospinal and sympathetic nervous systems.
8. Certain fetal remnants.

The abdominal cavity is technically considered to be a space enclosed by the bony and muscular walls of the body.

The peritoneal cavity, in contrast, is a potential space inside of the peritoneal membrane and between the viscera. (See Fig. 1, note B.) The peritoneal cavity has been described as a huge lymph sac. Being entirely surrounded by serous lining, it is normally empty except for the fluids elaborated by its walls.*

The peritoneum. This membrane derives its name from the Greek, *peri*, around, + *teino*, to stretch (see tonicity, tension,

* Authorities may be found who use the terms abdominal cavity and peritoneal cavity synonymously. By the definitions of these authorities³ (7) the kidneys lie outside of the abdominal cavity and are not, therefore, considered as abdominal organs. Such essential differences as to fundamental definitions clearly indicate the basis for much confusion.

FIG. 1. Ovoid trunk.

Note: (1) The abdomen extends downward from approximately the level of the nipples to that of the loins.

(2) The abdomen is completely filled with organs and the peritoneal cavity (space inside peritoneal membrane and between the viscera) is potential only.

(3) The body, without appendages or parts designed to support or move these appendages, is simply a huge ovoid.

(4) The abdomen extends well upward within the thoracic cage. Ribs serve to protect all organs of the supracolic division of the abdominal cavity.

N, nipple. D-D, upper surface of diaphragm. F.L., falciform lig. G.B., gall bladder. I. L. inguinal lig. (Poupart). U.B., urinary bladder. I.C., iliac crest. R.XI, eleventh rib R.L., round ligament. D.A., diaphragmatic attachment. P, peritoneal reflection. (His' model.)

tone). A smooth, lubricated surface is provided by the peritoneum as this structure stretches over or around the various abdominal organs, thus allowing free movement of the viscera in response to their functional activities.

The abdominal and peritoneal cavities contrasted. The expressions "intra-abdominal" and "intraperitoneal" are often used interchangeably in surgical literature. The surgeon, as a rule, when entering the abdomen also incises the peritoneum. Yet the differences between the two cavities should be kept in mind. Although both are situated in the region beneath the diaphragm, the abdomen proper ends with the pelvic inlet, while the peritoneal cavity extends well into the pelvis. The peritoneum has been spoken of as the inner lining of the abdomen, but it serves both more and less than this function (folds, raw areas). On cross-section the abdomen appears roughly oval or kidney-shaped but the peritoneal cavity consists of a series of complicated curves or waves formed as the membrane is reduplicated over the various structures suspended from the posterior or lateral abdominal walls. No actual space exists to mark the peritoneal "cavity," for the peritoneal surfaces normally lie in contact with one another unless the approximated walls have been forced apart by some force such as the surgeon's hands, blood, pus, air, or ascitic fluid.

"Intra"- and "extra"-peritoneal structures. The surgeon does not think of the peritoneal cavity as an empty space but as one which is literally filled with organs. For convenience, any organ whose walls are quite largely covered by peritoneum is termed "intraperitoneal" (jejunum, ileum) and one which has but slight contact with this serous membrane is referred to as "extraperitoneal" (kidneys, pancreas). The peritoneal membrane is to some degree in contact with every abdominal viscus. To explain this relationship between peritoneum and viscera the former has been compared to an inflated bag and the latter to objects pressed with varying degrees of force against it. Objects but lightly in contact with the inflated

bag would have little of their surfaces covered by bag-wall; while others, strongly pressed against it, would tend almost entirely to disappear and to have their walls almost completely covered by the walls of the bag. Yet in no case would the object described be actually within the bag itself.

Abdominal section signifies the act of cutting into the abdomen.

Laparotomy (Gr. *lapra*, flank, + *tome*, an incision) means literally an incision into the loin. By common usage, however, the term may signify an incision into any part of the abdominal wall. Thus a lumbar approach to the kidney is correctly termed a laparotomy while a transperitoneal exposure of the same organ is called a laparotomy only through a liberal extension from the original meaning of the word.

Celiotomy (coeliotomy: Gr. *koila*, belly; *koiloma*, a hollow) means opening the abdomen or into the peritoneal cavity.

Peritoneotomy (self-definitive) is the logical word to signify the act of cutting into the peritoneal cavity, but since the term proves difficult to pronounce it is infrequently employed.

These four terms: abdominal section, laparotomy, celiotomy, peritoneotomy, have come to be used interchangeably.

CLINICAL APPLICATIONS

A few clinical observations will serve to make clear the practical significance of these definitions.*

The Mesenteric
Stitch

A cross-section of a loop of jejunum or ileum shows that while clinically it may be permissible to refer to these divisions of the small bowel as being intraperitoneal the anatomical fact remains that the peritoneal membrane does not completely

* This transition from a consideration of definitions to that of clinical matters necessitates an explanatory note. To deal with practical points is, as stated, the primary object of this work. The text will consist, in reality, of a series of isolated paragraphs or entities, each written around a clinical heading as such a practical topic logically arises during the systematic study of the abdomen. These topics will be discussed at whatever length their importance seems to warrant, quite irrespective of proportion and arrangement. To be truly a postgraduate review the subject matter must be elective.

surround the intestinal wall. A "raw" or "uncovered" area exists at the line of attachment of the mesentery. The peritoneum is reflected upward as the right leaf of the mesentery;

FIG. 2. Mesenteric stitch.

1. "Raw" or "uncovered" area of intestine, where bowel wall is devoid of peritoneum.
2. Suture in position, ready to be tied.
- A. Method for closing raw surface during end-to-end anastomosis of bowel.
- B. Mattress, or u-stitch, employed to close the raw area in a single segment of bowel.

then over the bowel, constituting its outer coat; then downward as the left leaf of the mesentery. This arrangement leaves a small portion of intestinal wall devoid of a peritoneal covering. (Fig. 2.) When performing an intestinal anastomosis it is important that this raw or uncovered area be obliterated, for it has been established that failure of union, infection and stenosis are more frequently observed when this precaution has not been taken. The special stitch used to obliterate this area during an end-to-end anastomosis of bowel, is known as the "mesenteric stitch." It is usually of a mattress variety and therefore ensures a broad approximation of the mesenteric leaves, with a complete closure of the raw area. The sketch of this special mattress or "u-stitch" is self-explanatory. (Fig. 2.) In place of such a special method for taking the stitch the mesenteric gap in each loop may be closed separately by means of a simple transfixion stitch, taken between the two

leaves of the mesentery near the point at which they pass to the bowel wall. Marginal bleeding within the mesenteric gap may be controlled by either the mattress or simple stitch as the mesenteric surfaces are drawn together to close the raw surface. When uncontrolled, this marginal bleeding may lead to the formation of a hematoma which increases in size as the blood burrows between the leaves of the mesentery. Such hematomata are troublesome and are liable to infection, especially from organs of the putrefactive type. The potentialities of such a complication are obvious.

Reaching Abdominal Organs by Retro-peritoneal Routes

Certain other abdominal viscera have larger raw or uncovered areas than do the jejunum and ileum. With some, the surface not in contact with peritoneum is so extensive and is so located that it is possible to deal with them surgically without entering the peritoneal cavity. An extraperitoneal approach may be made to bladder (suprapubic cystotomy); to kidney (pyelotomy); to pancreas (drainage); to a retrocecal mass (appendiceal abscess); to liver (drainage of abscess confined to the falciform ligament (Osler⁴).

"Defenseless Areas" on the Posterior Abdominal Wall

Raw or uncovered areas exist upon the abdominal walls as well as upon viscera. The location and extent of these are made apparent by removing the abdominal viscera together with their membranous and ligamentous attachments. These uncovered areas mark upon the posterior wall the following (see Fig. 3); the root of the mesentery; the root of the transverse mesocolon; the root of the sigmoid mesocolon; an area behind the ascending colon; a similar area behind the descending colon; still another behind the posterior wall of the stomach (see triangular area of stomach); while other such zones mark the attachments of the coronary and falciform ligaments of the liver. These areas have been termed surgically the "defenseless" zones of the abdomen (Crile⁵), because infection readily sets in if these regions become contaminated by pathogenic microorganisms. The peritoneum itself, notwithstanding the surgeon's dread of peritonitis, is very resistant to infection, particularly from colon bacilli or other organisms of the putre-

fective group. Often a slight contamination of the peritoneum occurs without causing any clinical evidence of infection. The same degree of contamination, if occurring in one of the

FIG. 3. Empty cavity.

The abdominal organs have been removed, exposing the "raw" or "uncovered" areas of the posterior wall (zones devoid of peritoneum). (After Morris' Anatomy, from McMurrich's Development of the Human Body, Blakiston.)

F.L., falciform ligament. I.V.C., inferior vena cava. C.L., coronary ligament. E.F., epiploic foramen. D., duodenum. M., mesentery of small intestine. A., area of attachment of ascending colon. R., rectum. S.M., sigmoid mesocolon. D.C., area of attachment of descending colon. T.M., transverse mesocolon. O.B., omental bursa. MG., mesogastrium. E., esophagus. T.L., left triangular ligament.

so-called defenseless areas would quite certainly set up a troublesome and spreading inflammation within the retroperitoneal tissues. Great care should be taken while operating,

therefore, to avoid exposure of these uncovered zones to even slight contact with septic material. Again, every effort should be made to "peritonealize" (to cover with peritoneum) raw surfaces such as stumps of organs or suture lines which have been artificially created. In a word, just as the raw areas of organs need protection (see mesenteric stitch), so also do raw areas on the abdominal walls. When however an abscess or well-defined inflammatory process is already present within a retroperitoneal space, it is obvious that this should be drained retroperitoneally and every effort made to avoid spilling a large amount of septic material into the general peritoneal cavity. This fact, however, should not blind the surgeon to the established observation that the peritoneum is definitely more resistant to contamination than are the retroperitoneal tissues. (See Section IV: Pfieffer Phenomenon.⁶)

The abdominal and peritoneal cavities having been defined and differentiated, and their essential differences illustrated by clinical observations, a further approach to practical points will be made through a more systematic review of the various abdominal boundaries.

A. THE ROOF OR DIAPHRAGM

1. *Definition.* The body, without its appendages and the parts designed to support or move these appendages, is simply a huge ovoid mass (see Fig. 1, note c). This ovoid contains the body cavities separated from one another by partitions. The largest of these barriers is the diaphragm or midriff (Gr. *dia*, between, + *pragma*, partition; A. S. *mid*, middle, + *brif*, belly). This partition runs obliquely transverse to the long axis of the ovoid, separating abdomen and thorax.

The diaphragm is such an important boundary that the surgeon is well repaid for time spent in a detailed study of this structure. An investigation of the full meaning and accuracy of the synonym midriff, as is often the case in looking up the derivation of a word, serves to focus attention upon details of great significance. In what sense is the diaphragm a

The Thoracic
Extension of
the Abdomen

“middle partition?” It is often assumed that the level of the separation between abdomen and thorax is located along the costal margins (i. e., at the level of the diaphragmatic attachments). Thus, not infrequently the upper limit of the abdomen is thought of as extending anteriorly only to the level of the ensiform cartilage. It is true that below this point lies abdominal wall while above it lies thoracic wall. But it is equally true that the abdomen itself (the cavity) extends well above this point. The diaphragm does not, in reality, form a plane but is dome-shaped and over a considerable area abdomen and thorax overlap. This is a point of extreme importance, as will later be made apparent. The midriff, as its name might imply, forms a partition which roughly bisects the ovoid of the trunk at its greatest diameter. (Fig. 1, Line D-D.)

The accompanying illustration (Fig. 1, note 4) shows a typical illustration of the body and its viscera. Here in showing the thoracic viscera the pleural reflections are mapped out as they extend downward to the level of the diaphragmatic attachments. Upon looking at the *abdominal* viscera in this illustration, however, it is found that but a fragment of stomach and of liver may be seen, while there is no evidence of any spleen, pancreas, or right or left colic flexure. It is the continual observation of pictures presented from this angle which, if not actually giving an erroneous impression, at least favors an insufficient attention to the upward extension of the abdomen within the thoracic cage. Another illustration (Fig. 4) shows the trunk containing nothing but the abdominal organs. Here it may be observed that the abdomen extends upward virtually to the level of the nipples; that more than half of the total number of ribs to some extent overlies and serve to protect the abdominal cavity; and that the lower portions of the chest wall, while anatomically thoracic, are functionally also abdominal, to the extent that they act as walls for the abdomen. It will be noted that *the uppermost portion of the abdomen (the cavity) has no abdominal wall* but is covered by diaphragm, visceral pleura, lung, parietal pleura, ribs, and

FIG. 4. Abdominal viscera.

Compare with Figure 1. Note: (1) The abdomen extends upward virtually to the level of the nipples.

(2) More than half of the total number of ribs to some extent overlie and serve to protect the abdominal cavity.

(3) The lower thoracic wall serves functionally as a wall for the upper abdomen.

D, diaphragm. F.L. falciform ligament. D.C., descending colon. P.C., pelvic colon. P.R. peritoneal reflection. Ce. cecum. R.M., root of mesentery. A.C., ascending colon. G.B. gall bladder. (Thoracic markings omitted.) (His' model. From Schultze.)

intercostal muscles. The surgeon must deal with each of these layers as he enters the abdomen by the thoracic route.

How general is this disregard of the upward extension of the abdomen may be illustrated as follows: Ask the medical student or even the surgeon to place the flat of his hand over the hypochondrium and in most instances it will be observed that the palm is placed below the costal margins and largely within the epigastrium or a umbar region, rather than over the hypochondrium itself. The terms subcostal and hypochondriac should not be confused. The liver, for example, is an organ of the right hypochondrium yet it is not normally subcostal in location. In speaking of the hypochondriac regions the height to which they extend should be fully appreciated (Fig. 5). While the hypochondriac areas are abdominal topographical zones, they are traced, very largely, upon thoracic walls. (See Section 1: Topography.) Unless full recognition is taken of the fact that the organs of the hypochondriac zones lie for the most part well behind the ribs, an erroneous impression may be gained as to their accessibility. (See Section 11: Mobilization of the Splenic or Left Colic Flexure.) This overlapping of thorax and abdomen has an affect upon intra-abdominal pressures, physical signs, operative procedures, and in general (in manners later to be discussed) has an important bearing upon many phases of the work of the abdominal surgeon. It is of distinct advantage to think of the abdomen in terms of its upper extension and of the position of the diaphragm in terms of its domes as well as of its peripheral attachments.

2. *Origin.* The diaphragm, according to origin, has four parts, a ventral, a dorsal, a right lateral, and a left lateral. It arises chiefly (all of the ventral and most of the lateral portions) from that embryonic structure known as the septum transversum (Fig. 6). This is a mass of developing mesoderm which, as its name implies, lies across the long axis of the embryo. It marks the location of the primitive diaphragm and in addition gives rise to a portion of the liver (vascular

The Hypo-
chondrium

and connective-tissue elements), to the gastrohepatic ligament (the lesser omentum), to the coronary and falciform ligaments of the liver, and to the inferior portion of the pericardium

FIG. 5. Dissection of left hypochondrium to show relations of spleen to side wall of chest, diaphragm and adjacent viscera.

In addition to the portions of ribs, there has been removed a part of the base of the left lung, and a window has been made in the diaphragm almost down to the level of the costodiaphragmatic reflexion of the pleura. (From Cunningham's Anatomy.)

(this fact explains the relationship of the diaphragm to these structures). The lateral portions of the diaphragm spring, in part, from the lateral body walls. The dorsal portion arises from the posterior mesentery of the foregut. These four separate parts of the diaphragm grow towards one another until fusion has occurred.

In some instances fusion is incomplete, leaving a permanent communication between the peritoneal and the pleural cavities (congenital diaphragmatic hernia). Such weaknesses are found

FIG. 6. Diagrams of (a) a sagittal section of an embryo showing liver enclosed within septum transversum; (b) frontal section of the same; (c) frontal section of a later stage when the liver has separated from the diaphragm. (From McMurrich's *Development of the Human Body*, Blakiston.)

chiefly upon the left side, for fusion upon the right side is quite certainly ensured by the presence and early development of the liver. It is stated that of all diaphragmatic hernias one-sixth are congenital.⁷ Non-congenital hernias at this site are due to such traumata as bullet or stab wounds; or to rupture of the diaphragm from some sudden increase in intra-abdominal or intrathoracic pressures such as might occur with a crushing wound or with excessively vigorous artificial respirations, etc. Traumatic hernias have erroneously been termed false hernias. Although there is actually a herniation of abdominal contents no sac is present in traumatic cases, a circumstance which serves to differentiate these from congenital hernias. Diaphragmatic hernia should always be looked for in the presence of obscure abdominal symptoms. In general it is true that congenital diaphragmatic hernias have seldom been diagnosed before operation. They are, likewise, seldom cured since the defect often proves too extensive for successful

repair. Fascial plication or fascial transplantation has been advised. Successful operations have been reported in which the stomach was sutured over the hernia defect but this procedure has been condemned due to the frequency with which recurrence follows the procedure. The sac of a congenital diaphragmatic hernia may contain any structure normally located within the upper abdomen. The symptoms are those of the strangulation of some abdominal viscus. Among the symptoms are: pain after eating; pain in the left shoulder; suggestive physical signs such as abnormal tympany or gurgling sound within the chest; hematemesis; cardiac displacement; and dyspnea or dysphagia. Roentgen-ray pictures may prove invaluable.

**Operations for
Congenital
Hernias of the
Diaphragm**

When a congenital hernia is encountered but cannot be easily reduced during the performance of a laparotomy, no time should be wasted in opening the chest (Fig. 5). This often leads to spontaneous reduction of the mass or facilitates manual reduction (see Section 1, Intra-abdominal and Intra-thoracic Pressures). The mortality following operations by the purely abdominal route is stated to be 50 per cent and after those by the transthoracic approach 9.6 per cent.⁸ Even when reduction can be accomplished from below, satisfactory suturing of the diaphragm proves difficult. Suturing from above is relative easy due to the shape and accessibility of the diaphragm. When a herniation is known to exist it should be approached through the thorax, turning up a flap of the eighth and ninth ribs if necessary. When reduction proves difficult or if a more complete inspection of the abdominal organs seems necessary there should be no hesitation in cutting through the costal margins to extend the incision into the abdomen or in making a separate median or lateral abdominal incision.

**Herniation
through the
Foramen of
Morgagni**

A relatively uncommon type of diaphragmatic hernia is one occurring through the foramen of Morgagni, located between the sternal and the costal attachments of the diaphragm⁹ (see section on eponyms). Such a hernia is also

characterized as parasternal. Hernias through the foramen of Morgagni possess a double sac, one of peritoneum and one of pleura. The peritoneal sac, as it passes above the diaphragm to reach higher levels, dissects the parietal pleura away from the parietal wall and as the hernia enlarges still more the second sac, composed of pleura, is formed.

3. *The Descent of the Diaphragm.* In embryonic life the diaphragm is situated far above its final position. From the original location opposite the first cervical vertebra, it descends through successively lower cervical and thoracic levels. When the fourth cervical level has been reached a mass of muscle tissue grows into the primitive diaphragm and the structure then assumes something of its final musculomembranous character. The muscle tissue of the diaphragm, then, is chiefly derived from the fourth cervical myotome.¹⁰

This "high" position of the diaphragm is influenced in part by the size of the developing liver. At one time the liver weighs as much as the remainder of the body. Although rapidly diminishing in its relative size, the liver is still a voluminous organ at birth, occupying almost the entire upper half of the abdomen and extending to or below the level of the umbilicus and far into the left hypochondrium. From the first, liver and diaphragm are connected (both being derivatives of the septum transversum) and this association is never completely lost, for within the limits of the coronary and falciform ligaments, these organs retain their contact. This explains why the liver is, in part, retroperitoneal, and why a liver abscess may rupture into the chest or a foreign body may perforate the diaphragm to lodge in the liver without an invasion of the general peritoneal cavity.

In early embryonic life the thoracic cavity is relatively small and the abdominal cavity relatively large. Not only does the diaphragm occupy a high position, but so also do the liver, stomach, duodenum, pancreas and spleen. These organs all begin their development at levels above that of the adult abdominal cavity (above adult diaphragm). Thus from an

Relationship of
Liver and
Diaphragm

The Embryonic
Abdomen

embryological viewpoint the thorax may be considered in a sense as a portion of the abdomen. Indeed the lungs themselves are an outgrowth and secondary development from the gastrointestinal tract. This accounts for many similarities in behavior of the bronchial and the enteric musculature and in the vascular and nervous connections between lung and intestines. This high origin of the upper abdominal viscera has an important bearing upon the final arrangements of their blood vessels and nerves (see Section 11):

**The Phrenic
Nerves**

4. *Innervation.* The diaphragm receives nerve tissue simultaneously with the receipt of muscle tissue, while at cervical levels. Hence, when the adult or thoracic position is reached the pathway of the descent through the neck and thorax is marked by two long nerve trunks, the phrenic nerves, derived from the third, fourth and fifth (chiefly fourth) cervical segments. These nerves pierce the diaphragm and have terminal branches upon both the upper and lower surfaces of that structure, the richest supply being upon the lower surface.

The word phrenic is related to the term frenzy and is applied to these nerves because of the activity of the diaphragm during emotional states. The rapid, irregular and incomplete respirations and the associated cardiac irregularities observed during periods of emotional stress led to the early belief that the seat of the emotions was located within the thorax.

**Subdiaphragmatic
Irritation and
Shoulder Pain**

Certain clinical manifestations demonstrate that the phrenic nerves possess sensory as well as motor fibers. The introduction of gas into the peritoneal cavity (artificial pneumoperitoneum) is often immediately followed by severe pain in the supraclavicular regions or at the shoulder tips. Free blood (ruptured ectopic gestation) or enteral content (perforated peptic ulcer) may produce similar pain. It has been said that this symptom arises because the patient "misrefers" the condition from the actual seat of the sensory disturbance at the peripheral fibers of the phrenic nerve to the supposed seat of trouble in the region of the shoulder tip (that is, the area supplied by the third, fourth and fifth cervical segments: *nervus*

cutaneus colli, and nervi supraclaviculares, anterior, medius and posterior). Other explanations of this pain will be discussed when dealing with the signs and symptoms of abdominal

FIG. 7. Cervical sensory collar, showing distribution of sensory fibers of third, fourth and fifth cervical segments. (After Pottenger.)

diseases. The clinical evidence is undeniable that subdiaphragmatic irritation is followed by sensory phenomena: pain, soreness, altered responses to heat and cold, tenderness, hyperesthesia, vasomotor phenomena, in the cutaneous areas of the upper cervical segments. A "sensory collar" (Pottenger¹¹) marks the distribution of the sensory nerves. This area extends laterally from the side of the neck to the shoulder tip and vertically from the ramus of the mandible to the upper level of the third rib anteriorly. (Fig. 7.)

The innervation of the diaphragm from cervical levels illustrates an important rule, namely that regardless of subsequent descents, rotations or other changes in position, an organ always retains the central nerve connections which were established during embryonic life. Some of the most valuable diagnostic signs and symptoms are initiated through

The Cervical
Sensory Collar:
Cutaneous
Phenomena of
C₃, C₄ and C₅

Embryonic Nerve
Pathways

impulses traveling over these nerve pathways, which mark the changes in position the organs have undergone during their development. (See testicular tenderness with kidney disease).¹²

Peripheral and
Sympathetic
Innervations
of Diaphragm

After the diaphragm has descended to its final position the phrenic nerves are joined, according to some authorities, by branches of the ninth, tenth, and eleventh thoracic nerves and these, innervating the periphery of the muscle, allow some motion of the diaphragm even after a total destruction of both phrenic nerves. The anatomical section of one or both phrenic nerves may take place during a bilateral dissection of the neck as for tuberculous glands or malignant metastases. Physiological section may occur during brachial plexus nerve block (regional anesthesia). A bilateral blocking of the brachial plexus has repeatedly occurred without fatal results.¹³

The diaphragm possesses, in addition, a sympathetic plexus. This includes the phrenic ganglion situated at the junction of the right phrenic nerve with the diaphragmatic plexus. Little information is available concerning the exact function of these sympathetic nerves or their clinical significance.

The Vagus
Nerves

5. *Structures Piercing the Diaphragm.* The roof of the abdominal cavity is pierced, not only by the phrenic nerves, but also by the vagus and splanchnic nerves. The name vagus means "wandering" and is given to those nerve trunks which wander through the neck, thorax and abdomen, innervating adjacent viscera but having no connections with the central nervous system except within the medulla. The vagi innervate the entire intestinal tract, with all its derivatives, from the level of the pharynx to that of the colon. The vagi represent the bulbar portion of the autonomic or parasympathetic division of the involuntary nervous system. (See Section II: Visceral Neurology.)

The Splanchnic
Nerves

The splanchnic nerves, greater, lesser, and least, represent the sympathetic or thoracolumbar innervation of the intestinal tract. The word splanchnic is derived from the Greek *splanchnon*, a viscus (especially any large abdominal organ) and refers to nerves passing from their origins from the thoracic

portions of the sympathetic paravertebral ganglionated trunks to reach the upper abdominal viscera. The greater splanchnics, right and left, arise from the fifth to the ninth thoracic levels, course over the bodies of the lower thoracic vertebrae to pierce the right and left crura of the diaphragm respectively, and pass to the celiac ganglion or solar plexus. The lesser splanchnics follow the same course and arise from the tenth and eleventh thoracic levels of the ganglionated trunks. The least splanchnics arise from the twelfth thoracic level or as branches of the lesser trunks.

The celiac plexus (Gr. *koeloma*, belly), to which these nerves pass, originally occupies a position opposite the levels from which the splanchnic nerves arise. The recession of the diaphragm, however, forcing the plexus downward, converts the splanchnic trunks into definite cords of considerable length (Fig. 8).

The Celiac
Ganglion

The foregoing considerations regarding the phrenic nerves, vagi, and splanchnic trunks, make it clear that the entire alimentary tract, from pharynx to distal third of transverse colon, together with all derivatives of this portion of the enteral canal, including lungs, liver, and pancreas, is innervated solely through trunks which originate in or pass through the thorax. Obviously, therefore, the surgeon should consider the thorax to be, at least in part, a functional division of the abdomen. A glance at anatomical pictures of the cavities of the trunk makes it apparent that this innervation of upper abdominal viscera by way of the thorax could not be otherwise (Fig. 8). The organs of the supracolic division of the abdomen lie well beneath the domes of the diaphragm and above the level of the dorsal attachments of this structure. Thus nerves passing to or from these organs (visceral afferent or efferent trunks) would have to pass in a *downward* course to get beneath the margins of the diaphragm and not puncture this barrier on their way to join the cerebrospinal nervous system. But since the true course of these nerves is *upward* (the spinal cord ending at the level of the first lumbar vertebra) it is obvious

Thoracic Course
of the Abdominal
Nerves

that the diaphragm must be punctured before the spine is reached. If the nerves of the upper abdominal organs passed to lumbar (abdominal) levels, reflex phenomena from these

FIG. 8. Thoracic course of abdominal nerves. The roof of the abdomen, viewed from above, showing the nerves which pierce the diaphragm. Note the domed shape of the diaphragm.

viscera could not occur within the anterior abdominal wall (innervated by thoracic nerves) but would be observed at levels below that of Poupart's ligament (the sensory level of the first lumbar segment) or in the thighs and legs.

Tumors, inflammations, or other disorders of pulmonary, pleural, cardiac, pericardial or mediastinal origin, may press upon or otherwise *irritate the abdominal nerves in the thoracic part of their course* (Fig. 8). In so doing the thoracic disorder will set up the same reflex phenomena as though the disease were actually located below the diaphragm. Thus, for example, a dissecting aneurysm may produce a boardlike rigidity of the abdomen and a right-sided diaphragmatic pleurisy may closely simulate an acute cholecystitis. The thoracic disorders may provoke additional phenomena which prove of value for differential diagnosis but a simple inspection or palpation of the abdominal wall, without regard to an adequate history or to the examination of other regions of the body, would reveal a perfect "surgical abdomen." Not only may the abdominal disease be simulated, but in large part the identical mechanism is active and the same nerves involved. All too frequently an operation upon the "surgical abdomen" reveals no abdominal pathology while the subsequent course and the accumulation of more complete data disclose that the actual seat of disease is within the thorax (pneumonia simulating acute appendicitis). Such elements of confusion and methods for differential diagnosis will subsequently be more fully discussed. (See section on Visceral Neurology.) The clinical importance of these preliminary anatomical details will be referred to again and again throughout the remaining portions of this book.

Thoracic Disorders Producing Abdominal Signs and Symptoms

To summarize: It has been noted that in early embryonic life the diaphragm is situated at cervical levels and that the region later known as thorax is largely filled with abdominal organs. It has been pointed out that the lungs are an outgrowth and secondary development from the enteral tract. It has been observed that the nerves of the upper abdominal viscera reach the abdomen only after passing through the thorax. The fact has been stressed that the abdomen extends upward well within the thoracic cage. Thus, embryologically, physiologically and anatomically the thorax may be considered, in a very

The Abdominal Surgeon and the Thorax

important sense, as an integral part of the abdomen. The diaphragm is not the hard-and-fast barrier which it is often considered to be, separating the domain of the abdominal surgeon from that of the physician. To understand the abdomen, both for diagnosis and treatment, it is necessary to study not only the abdomen itself but the thorax as well and to focus attention upon all structures which pierce the roof of the abdominal cavity. To study those structures entering or leaving the abdomen and to thus investigate the abdominal cavity as an integral part of the individual and from the perspective of distance is essential to a thorough understanding of the work of the abdominal surgeon.

**Other Structures
Penetrating the
Diaphragm**

A more comprehensive list of the structures (thirty-two) which pass through this incomplete and moveable roof of the abdomen is as follows:¹⁴

The phrenic nerves.

The vagus nerves.

The sympathetic ganglionated trunk.

The greater splanchnic nerves.

The lesser splanchnic nerves.

The least splanchnic nerves.

The esophagus.

The aorta.

The lymphatics.

The inferior vena cava.

The thoracic duct.

The superior epigastric arteries and their venae comites.

The musculophrenic arteries and their venae comites.

The last pair of subcostal arteries and veins.

The venae azygos.

The twelfth thoracic nerves.

6. *Attachments.* Equally important with the study of a "history" of the diaphragm (its development) is that of its adult attachments. The surgeon must know the normal levels of the diaphragmatic domes and how these may be altered by an empyema, subphrenic abscess, or paralysis of a phrenic

nerve; he should know any differences in level between the two domes and the effects upon these of forceful inspiration and expiration. It is only through accurate knowledge of such details that roentgen-ray films or fluoroscopic shadows may be satisfactorily interpreted, the results of percussion evaluated, and proper sites selected at which to enter the highest levels of the abdomen or to drain the lowest limits of the pleural cavities.

The roof of the abdominal cavity is not horizontal but oblique, and the diaphragm is in part a posterior wall as well as a roof (Fig. 9). Anteriorly the diaphragm is attached at the level of the xiphoid process, posteriorly the level is that of the first lumbar vertebra (see crura). A plane constructed between these two points shows that the diaphragm has a tilt which is approximately equal, though in an opposite direction, to that of the pelvis. Laterally the diaphragm is attached to the lower six costal cartilages and follows the obliquity of the costal margins. A line perpendicular to the plane of the midriff, as one perpendicular to the plane of the pelvic inlet, would pierce the umbilicus (60° from the horizontal). Because of this arrangement, *the posterior abdominal wall of the adult is less than half the length of the anterior wall* (Fig. 9), a fact of significance to the surgeon as he seeks to orient himself within the abdomen.

The Tilt of the
Diaphragm

Normally the upper surface of the diaphragm reaches the following levels on the bony skeleton during expiration.¹⁵

The Thoracic
Floor

a. When viewed from the front:

The midline: to the xiphosternal notch.

The right midclavicular line: to lower surface of the fourth rib.

The left midclavicular line: to upper surface of the fifth rib.

(i.e. the right side is from $\frac{1}{2}$ to 1 inch higher than the left.)

b. When viewed from the back.

The midline: level of the spine to the eighth thoracic vertebra.

FIG. 9. Tilt of diaphragm.

The posterior abdominal wall is less than half the length of the anterior abdominal wall. Note how completely the abdominal cavity is filled with contents. The peritoneal cavity is potential only.

D, diaphragm. L, left lobe of liver. R. VII, seventh rib. S, stomach. S.I., small intestine. S.C., sigmoid colon. I.L., inguinal ligament (Poupart). I.M., iliopsoas muscle. L.A., levator ani; P.M, piriformis muscle. Q.L, quadratus lumborum. D.C., descending colon. L.K, left kidney. R. XII, twelfth rib. R. XI, eleventh rib. SP, spleen (From Schultze.)

Right side: level of the angle of the scapula.

Left side: To a point one inch below the angle of scapula.

Posteriorly, neither the upper nor the lower limits of the liver may be mapped out by percussion, for above, the liver is covered by lung and below, liver dullness merges with kidney dullness.

7. *Movements with Respiration.* The variations from these upper limits of the diaphragm which occur during normal respiration are not great, for the diaphragm, although in general a dome-shaped structure, does not move en masse since its central portion is tendinous rather than muscular. The movements take place between the central portion and the peripheral attachment. The two sides being separately innervated, right and left, may function separately.

8. *Surgery of the Diaphragm.* A clear visualization by the surgeon of the shape of the diaphragm, its relations to the skeleton, and of the manner in which thorax and abdomen overlap is essential to a skilful passage of an aspirating needle in the search for a subphrenic abscess. Before passing through the midriff to reach the abdomen the needle point must traverse, for various distances, the pleural cavity. As the needle is entered through successively higher sites upon the body wall between the levels of the diaphragmatic attachments and domes, greater and greater distances within the thoracic cage must be traversed. As a rule the attempt to localize subdiaphragmatic pus is made by first thrusting the needle through the ninth or tenth intercostal spaces on a line with the angle of the scapula, or in the midaxillary line. If this thrust is unsuccessful, subsequent passages are made through the eighth, seventh, or even sixth intercostal space (the diaphragm being usually elevated above its normal position by the abscess. In passing through the pleural cavity a serous or even purulent fluid may be encountered, for such an accumulation is a fairly constant accompaniment of subdiaphragmatic abscess, and only when the midriff has been punctured will the thick pus which is

Exploratory Puncture for Sub-diaphragmatic Abscess

sought be encountered. It is always dangerous to pass a needle into such an accumulation of pus and this should be done only in an operating room and when the surgeon is prepared for an immediate operation if pus is found. The needle should never be passed from the peritoneal, but always from the pleural side.

The "Negative-
Pressure"
Aspirating
Needle

When searching for a subdiaphragmatic abscess by means of an aspirating needle it proves of advantage to employ the "negative pressure needle" or to aspirate "with vacuum in hand." As the needlepoint reaches the deeper tissues the plunger of the aspirating syringe is drawn backward some distance, thereby creating a partial vacuum within the barrel and needle. Now as the needle point is advanced there is a strong suction in the direction of the syringe and as the abscess is reached the pus pours or springs into the barrel and the abscess is at once revealed. This is distinctly an advantage over the method of repeatedly advancing the needle, then testing, for the latter procedure requires multiple needle thrusts and may produce some bleeding so that as the blood is drawn into the syringe there remains some question as to whether the syringe content is the result of trauma or the abscess has actually been located.

Subphrenic
Pyopneumothorax

One of the surgeon's most difficult problems in differential diagnosis is that of distinguishing between pus located beneath the diaphragm (subphrenic abscess) and that above the diaphragm (an empyema). The subphrenic abscess, by pushing the diaphragm upward, and particularly because of its frequent association with the large gas bubble (Fig. 10) caused by infection with a gas-forming (putrefactive) organism or the communication with a perforation within a hollow organ, may closely simulate a collection of pus and air within the pleural cavity (pyopneumothorax). Indeed a subdiaphragmatic abscess, if not promptly treated, regularly excites the formation of a pleural exudate and tends to rupture through the diaphragm into the thorax, adding greatly to the confusion in the clinical picture and the difficulty in reaching a correct diagnosis.

A subphrenic abscess associated with gas formation is termed a subphrenic pyopneumothorax.

A subphrenic abscess may be defined as "any abscess in

Subphrenic
Abscesses

FIG. 10. Right subphrenic abscess following purulent appendicitis showing area of dullness and the shifting tympany from the large gas-bubble. The gas was formed by the colon bacilli. (From Babcock's Textbook of Surgery, Saunders.)

contact with the under surface of the diaphragm, except one situated within the substance of the liver or spleen."⁷ Sub-diaphragmatic abscesses are intraperitoneal in more than half the cases and in about half are associated with a gas bubble; over three-fourths are situated on the right side. Retroperitoneal abscesses are confined within the boundaries of the coronary or falciform ligaments, and those on the left side, within the omental bursa. The onset is usually insidious, blending gradually with the primary condition, the etiological factor being, in most instances, a perforation of a peptic ulcer, a gangrenous appendix, or the rupture of a liver abscess.

The pus is ordinarily deep seated, causing symptoms which are indefinite and confusing. Diagnosis is particularly difficult when the abscess is behind or below the liver (the posterior type) or the condition complicated by a secondary empyema. When the abscess points forward the epigastrium may bulge and be tender; when pointing posteriorly the anterior wall may show no signs, the bulge being then in the lower costal area, or loin. (See obliquity of diaphragm.) Enlargement of the liver downward does not ordinarily occur with subphrenic abscess and this condition, when present, favors the diagnosis of liver abscess. Usually the abdominal swelling, when visible or palpable, does not move with respiration. The signs and symptoms are those of deep-seated suppuration anywhere in the body: hectic fever, rigors, rapid pulse, leucocytosis, associated with dyspnea, abdominal distention, local bulging, and elevation of the diaphragm, and an upward (but not a lateral) displacement of the heart. An infrequent sign, but one valuable when observed, is the presence of inflammation about the umbilicus due to an extension of the inflammatory process along the round ligament of the liver.

**Differentiation
of Empyema and
Subphrenic
Abscess**

With empyema, in contrast, there is a lateral displacement of the heart; the process does not involve both abdomen and chest, but is limited to the thorax alone; the thoracic condition involves, not only the lower pleural cavity, but almost the entire side of the space. The costophrenic angle is obliterated, showing examination upon roentgen-ray a flat or fluid line and downward displacement of the diaphragm. The most important evidence in the differentiation is the history. A primary empyema is almost always the complication of a pneumonia or influenza, while with equal frequency a sub-diaphragmatic abscess is the result of the perforation of a peptic ulcer, of appendicitis, or is secondary to a liver abscess.

**Roentgen-Ray
Interpretation**

It is not always easy to tell from roentgenograms when the diaphragm is at normal and when at abnormal levels. The angle from which the picture is taken may result in distortion. Fluoroscopic exposures and stereoscopic plates prove easier

to interpret in this respect. Roentgenograms taken to demonstrate the location of a collection of pus in relation to the diaphragm must be interpreted more through the relative height of the two diaphragmatic domes (right slightly higher in the normal), the degree and manner of obliteration of the costophrenic angle, and the degree and direction of displacement of the heart, than through the demonstrated relationship between diaphragm and bony skeleton.

The diaphragm tends to be elevated by subphrenic abscesses, depressed by empyema or pleural effusions, and immobilized by either. Any position of the diaphragmatic domes markedly away from the abdomen is termed an eventration of the diaphragm (Gr. *e*, away, + *venter*, belly). The most marked degree of eventration is that which occurs with paralysis of a phrenic nerve.

Eventration of the
Diaphragm

Methods for dealing surgically with the diaphragm, both by the abdominal and the thoracic routes of approach, have previously been discussed. (See Diaphragmatic Hernia.)*

*The next installment will appear in the February issue of the Journal and will deal with the study of the floor and walls of the abdominal cavity.

EPONYM

GIOVANNI BATTISTA MORGAGNI

- Eponym:** "Hernia through the foramen of Morgagni."
Parasternal hernia. Hernia diaphragmatica vera sternalis.
- Name:** Giovanni Battista Morgagni (pronounced mor-gahn'yce).
In Latin writings: Johannus Baptista Morgagnus.
In English writings: John Baptist Morgagni.
- Nativity:** Forli, Italy.
- Birth and Death:** Born February 25, 1682, Died December 6, 1771.
- Connections:** Member of Academy at Forli.
Demonstrator of Anatomy at Bologna, replacing Valsalva.
Occupied chair of the Theory of Medicine and chair of Anatomy at Padua.
- Education:** Early education received in Forli. Here his great knowledge of literature contributed to his election to the academy at the age of fourteen.
Received M.D. degree at Bologna in 1701.
- Eponym Source:** Morgagni wrote on this type of diaphragmatic hernia in letter 54 of his book "De Sedibus et Causis Morborum per Anatomen Indagatis," a set of letters, seventy in number, published as five volumes in his seventy-ninth year, and a work written in an unusually interesting and informal style.
- Other Writings:** "Adversaria Anatomica" is the chief work in addition to the "De Sedibus."
- Discussion of Eponym:** Morgagni's description of this hernia is very complete being more informative on the subject than most present-day discussions.
A score or more anatomical terms are associated with the name Morgagni, including:
- | | | |
|----------------|---------------|-----------------|
| M.'s appendix | M.'s tubercle | M.'s valve |
| M.'s cartilage | M.'s caruncle | M.'s concha |
| M.'s cataract | M.'s column | M.'s fossa |
| M.'s crypts | M.'s foramen | M.'s globules |
| M.'s frenum | M.'s glands | M.'s lacuna |
| M.'s humor | M.'s hydatid | M.'s sinus |
| M.'s nodule | M.'s prolapse | M.'s ventricle. |
- Points of Interest:** Morgagni was so capable a teacher and anatomist that at Bologna he had the reputation of being one of the first anatomists of Europe. He gave up teaching to practice medicine at Forli but was dissatisfied because this left no time for research. Hence in 1712 he went to Padua.
Taught at Padua for nearly sixty years, bringing great fame to the university.
Lived to an advanced age, dying in his ninetieth year.
Virchow said that Morgagni "introduced the anatomical idea into medical practice."
- Special References:** Biography from Reference Handbook of the Medical Sciences. Vol. 6; also Walsh..
James J. Morgagni, the Father of Pathology.
Eponym from De Sedibus et Causis Morborum per Anatomen Indagatis, Venice, 1762, letter 54.
Virchow, R. Morgagni und der anatomische Gedanke, Berlin, Hirschwald, 1894.
Bowditch, Henry I. A Treatise on Diaphragmatic Hernia. Buffalo, Jewett, Thomas, 1853. See pp. 12 and 13, also p. 17 for illustration.
- NOTE:** The author wishes to express indebtedness to Dr. Lewis Francis Ellmore for aid in the study of this eponym.

upon the drawing asunder of the fleshy fibres, and upon the giving way of the membranes, the stomach, or some part of the intestinal tube, or any other viscus, may pass over from the belly into the thorax.

Thus (beside the passage of the œsophagus of which I shall speak afterwards) I see it is related by Platner (c); that some part of the colon, but a still larger part of the omentum, and pancreas, was carried up through that passage which transmits one of the intercostal nerves; and this happen'd after very violent pains of the intestines.

Thus also, anteriorly, betwixt the fibres that come from the xiphoid cartilage and the neighbouring fibres, there generally is an interval through which something similar may happen: and I even suspected this to have happen'd in a husbandman, in whom I heard that Leprotti saw, at Rome, part of the intestine colon carried up, through the middle and anterior part of the diaphragm, in so great a quantity as to equal a span, when extended.

But as I afterwards heard, from those who had dissected the body, that neither this intestine, nor the foramen, the diameter of which was two thumbs breadths, and through which this part went out and came in, show'd any sign of foregoing violence or disorder, and that the man died in decrepit age, from a manifest injury within the skull; I chose rather to suppose that it had been thus from the original formation:

FIG. 11C. Morgagni's original discussion of the foramen which bears his name.

EPONYM

FRANCOIS POUPART

- Eponym:** "Poupart's ligament." Ligamentum inguinale.
- Name:** François Poupart (pronounced poo-part).
- Nativity:** Mans, France.
- Birth and Death:** Born 1661; Died October 31, 1709.
- Connections:** Admitted to Academy of Sciences as a pupil of Mery in 1699.
Conducted his researches privately while engaged in the practice of his profession.
Held no teaching chair.
- Education:** Early education, especially in philosophy and humanities, at the Oratory at Mans.
Specialized in the study of surgery and anatomy at the Jardin du Roi.
Passed the examinations in surgery at the Hotel Dieu, Paris, with high grades.
Received his doctor's degree at Rheims.
- Eponym Source:** In 1705 Poupart made an oral communication to the Royal Academy of Sciences in Paris, of which a note is preserved on page 51 of the History of the Academy for that year, describing the ligament.
- Other Writings:** Wrote a "Complete Surgery."
Contributed to *Journal des Savants* and to *Journal of the Academy of Sciences*.
Also wrote on mussels, the leech, and the apparition of spirits.
- Discussion of Eponym:** Many authorities declare that Poupart's description of the ligament bearing his name was neither new nor exact.
Even though the B.N.A. (Basle Anatomical Nomenclature) dropped this eponymic term, students and practitioners will probably always think of the ligamentum inguinale as "Poupart's ligament."
- Points of Interest:** Poupart was an independent worker engaged in a poorly paying practice, and although he carried on his investigations without subsidy, it has been said that he "never allowed his poverty to interfere with his researches."
- Special References:** Biography from Reference Handbook of the Medical Sciences. Vol. 7.
Eponym from Histoire de L'Academie Royale Des Sciences Année m^oc^oc^ov, page 51 (page 64 of the Amsterdam edition published in 1707).
Excellent summary of the historical aspects of Poupart's ligament in *J. Anat. & Physiol.*, Loud, 33: 493, 1898-9.
NOTE: The author wishes to express indebtedness to Dr. Lewis Francis Ellmore for aid in the study of this eponym.

64 HISTOIRE DE L'ACADEMIE ROYALE

V.

M. Poupart a parlé de deux gros Ligaments ronds, fort visibles, puisque dans les grandes personnes ils sont longs de plus d'un demi-pied, & dont cependant les Anatomistes n'ont point traité, apparemment parce qu'ils n'en

ont pas connu les usages. Ils sont attachez par un bout sur la crête de l'Os des Iles, par l'autre bout sur la crête de l'Os Pubis, & le milieu porte à faux. Ils font la fonction d'os en cet endroit, car ils soutiennent les trois grands Muscles de l'Abdomen, c'est-à-dire, l'Oblique externe, l'Oblique interne, & le Transversé. Leurs fibres tendineuses à peu près parallèles entre-elles vont s'attacher à ces Ligaments. Ils sont situés immédiatement au dessous des Anneaux.

La pensée de M. Poupart est qu'ils peuvent soutenir & rompre en partie l'impulsion que de grandes toux, des sauts violents &c. donnent aux Intestins, & par-là les empêcher de s'insinuer entre les Anneaux, & de former des Hernies. De plus ces Ligaments tenant lieu d'Os, quelques Os que la Nature eût mis à leur place, le Ventre en auroit eu moins de liberté de s'étendre, sur tout dans les grossesses. Par ces raisons, M. Poupart appelle ces deux Ligaments *Suspenseurs de l'Abdomen*.

FIG. 12B.

QUESTIONNAIRE

An ideal method for study is through the use of direct questions and answers. It proves far more difficult to formulate concise answers to specific questions than simply to possess a vague comprehension of subject matter which has been reviewed.

In order to adhere to the purpose of this book and to make of it a postgraduate course, rather than a text for casual reading, a questionnaire is appended to each chapter. Its aim is to focus attention upon salient points, to excite curiosity, to encourage reference to source books, to promote individual thought.

1. What is the abdomen? Is it a section or segment of the body? Is it a cavity? Is it a portion of the body wall? Is it a combination of wall and cavity?
2. What does the word abdomen mean; what is its derivation?
3. Can the terms abdomen and abdominal cavity be used interchangeably? If not, what are the differences in meaning?
4. Give a list of the structures found within the normal abdominal cavity.
5. What is the peritoneal cavity? Can the terms abdominal cavity and peritoneal cavity be used interchangeably? If there are differences between the two cavities, what are they? What is the derivation of the word peritoneum?
6. What is meant when it is said that the peritoneal cavity is potential only?
7. Sketch a cross section of the peritoneal cavity and of the abdominal cavity at any fixed level.
8. What is an "intraperitoneal" structure? An "extraperitoneal" structure?
9. What does the anatomist mean when he says that no organ is actually intraperitoneal?
10. What is the normal content of the peritoneal cavity?
11. What is the meaning of the following: abdominal section; laparotomy; celiotomy; peritoneotomy? Which of these words may be used interchangeably?
12. What is meant by the expression "the raw or uncovered" area of the jejunum and ileum?
13. Draw a cross section of jejunum or ileum showing the relationship between peritoneum and bowel wall.
14. What is a "mesenteric stitch?" What is the object of such a stitch? Varieties of the stitch? Give illustrations.
15. What organs may be approached by retroperitoneal routes?
16. Differentiate and localize: (a) retroperitoneal subdiaphragmatic abscesses; (b) intraperitoneal subdiaphragmatic abscesses.
17. What is meant by the expression "the defenseless zones" of the abdominal wall? Explain.
18. What proportion (roughly what percentage) of the posterior abdominal wall serves as a site of attachment for abdominal organs?
19. What intraabdominal structures are attached to the anterior abdominal wall?
20. When the abdominal organs and their ligamentous or peritoneal attachments have been severed from the posterior abdominal wall, what areas of the abdominal wall are left devoid of peritoneum? Give list.
21. What is meant by the expression "to peritonealize a raw surface?"
22. What is the derivation of the word diaphragm? Midriff?
23. Signify upon the anterior abdominal wall the upper limit of the abdomen.
24. In what manner and in what degree does the abdomen extend within the thoracic cage?
25. Through what layers must the surgeon pass to enter the abdomen by the thoracic route?

26. Distinguish between the subcostal region and the hypochondrium.
27. Name the complete boundaries of the hypochondriac region.
28. How many ribs overlie the abdominal cavity?
29. Describe the origin of the diaphragm.
30. What is the septum transversum?
31. To what adult structures does the septum transversum give rise?
32. What is the cause of congenital diaphragmatic hernias? Upon which side are these most common?
33. What percentage of diaphragmatic hernias are congenital?
34. Give the causes of traumatic diaphragmatic hernias.
35. What is meant by a false diaphragmatic hernia? Is this term well selected? Discuss.
36. Give methods of repairing a large defect in the diaphragm.
37. What are the usual contents of diaphragmatic hernias?
38. Give the chief signs and symptoms of diaphragmatic hernias.
39. By what routes may a diaphragmatic hernia be approached surgically? Discuss. advantages and disadvantages of each. Give the mortality with each.
40. What is a hernia through the foramen of Morgagni? Why does this type of hernia possess two sacs? Of what are these sacs composed?
41. At what level does the diaphragm originate?
42. Since the diaphragm occupies at various periods of development each of the cervical and upper thoracic levels, why is its chief innervation derived from the fourth cervical level?
43. From what myotome is the muscle of the diaphragm derived?
44. Discuss the anatomical relationship between diaphragm and liver. State some clinical observations based upon this relationship.
45. How may a foreign body get into the abdominal cavity through the diaphragm without entering the general peritoneal cavity?
46. In what sense may the thorax be considered a functional part of the abdomen?
47. What are the derivatives of the gastrointestinal tract?
48. Give a list of thirty or more structures which pass between abdomen and thorax.
49. What is the derivation of the word phrenic?
50. Explain the shoulder pains due to subdiaphragmatic irritation.
51. Give a sketch of the specific nerve pathways involved in the above.
52. What intra-abdominal conditions most commonly give rise to shoulder pain?
53. What other phenomena are noted in the cervical region in association with shoulder pain of abdominal origin?
54. What is meant by the term "the cervical sensory collar?" Give its limits.
55. State the innervation of the diaphragm in addition to that through the phrenic nerves.
56. What is the derivation of the word vagus? Splanchnic?
57. What are the splanchnic nerves? How many splanchnic nerves are there? Give their origin and course.
58. What is the vegetative nervous system? The autonomic nervous system? The sympathetic system? The parasympathetic system?
59. What parts of the alimentary tract are innervated by the vagi? By the splanchnics?
60. What is the celiac ganglion?
61. What part of the enteral canal is innervated by nerves which originate in or pass through the thorax?
62. What abdominal symptoms are caused by pressure upon, or irritation of abdominal nerves in the thoracic part of their course?
63. What thoracic disorders most commonly simulate abdominal diseases?

64. What is meant by "the surgical abdomen?"
65. Can thoracic disorders produce this condition?
66. Why do so many of the afferent and efferent trunks of the abdominal viscera pierce the diaphragm?
67. What sensory area is innervated by the first lumbar spinal segment?
68. In what sense is the diaphragm a barrier separating the domain of the abdominal surgeon from that of the physician?
69. Why is it necessary to study the thorax in order properly to understand the abdomen?
70. What is meant by the statement that "embryologically, physiologically, and anatomically the thorax may be considered, in a sense, an integral part of the abdomen?"
71. What is the relative length of the anterior and of the posterior abdominal walls?
72. What is meant by the tilt of the diaphragm?
73. Name the normal levels of the domes of the diaphragm (a) when viewed from the front; (b) when viewed from the back.
74. Describe the movements of the diaphragm with normal breathing.
75. Name the sites at which a needle may be introduced in searching for a subphrenic abscess. To what depth must the needle be thrust to enter the abdomen?
76. What abnormality is usually found in the pleural cavity when a subphrenic abscess is present beneath?
77. Is exploratory puncture for a subdiaphragmatic abscess safe? When may it be made; when is it contraindicated?
78. What is meant by the expression "negative pressure aspirating needle?"
79. What is a subphrenic pyopneumothorax?
80. What is meant by the gas bubble of subphrenic abscess? Its origin? Frequency?
81. Give a differentiation between an empyema and a subphrenic abscess.
82. Classify subphrenic abscesses. Give usual causes for these abscesses. Why is the history of paramount importance?
83. What are the signs and symptoms of subdiaphragmatic abscess?
84. Give the roentgen-ray evidence which points to subphrenic abscess.
85. What is eventration of the diaphragm?

No. 2

CONDUCTION ANESTHESIA FOR MINOR SURGERY*

GEORGE P. PITKIN, M.D., F.A.C.S.

BERGENFIELD, N. J.

IT IS interesting if not instructive to know that in 1915 there were ten articles published in the American medical literature on local, conduction and spinal anesthesia. In 1920 there were twenty-three contributions. In 1929 one hundred twenty-two articles were published by American authors. During the same year European physicians contributed more than twice this amount. For the most part these articles had been written by and for the specialist. There has been little or no attempt made to describe a simplified technic that could be readily understood by the general practitioner.

There were three medical colleges in the United States teaching local and conduction anesthesia in 1920. This may explain to some extent why this form of anesthesia is not more generally used by the profession. In fact the majority of general practitioners have little or no conception of the dosage, advantages, or technical use of novocaine anesthesia. This is well exemplified by the answers obtained from questionnaires sent to several hundred physicians in country practice, without hospital associations, with the inquiry: "How many cubic centimeters of a 1 per cent novocaine solution would you consider it safe to inject into a patient weighing 150 pounds." Two hundred four replies were received: A trifle over 50 per cent of the physicians were kind enough to answer. Of these 63 per cent considered 2 to 4 c.c. a maximum dose. Sixteen per cent thought it

safe to use from 2 to 10 c.c.; 8 per cent would use from 5 to 15 c.c.; 6 per cent not over 20 c.c.; 3 per cent up to 30 c.c. One replied "use enough." These replies demonstrated quite conclusively that a vast majority of the practicing physicians of the country have not had adequate training in this branch of anesthesia, either during their college course or their hospital internship; especially, when one considers that Babcock, Farr, Lowsley, Jones and the author have repeatedly used 400 to 500, and even 600 c.c. of a 1 per cent novocaine solution without causing untoward effects, and in none of the cases were toxic symptoms observed.

Local and conduction anesthesia is very rapidly becoming the anesthetic of choice, as is shown not only by the increasing number of articles that are written each year, but by the fact that in 1908, 2 pounds of novocaine were sold in the United States, and at present there is a consumption of approximately 2000 pounds a week. Practically every university hospital in the United States is now using routinely some form of local or spinal anesthesia, whereas in 1920 the technic was taught in three of our colleges.

For some unknown reason local and conduction anesthesia has been looked upon as a highly specialized art, far too technical and dangerous to be practiced by the untrained. Possibly this conception regarding the relatively small dose of 2 to 6 c.c. was due to the fact that the only available source of novocaine solution

*Submitted for publication January 7, 1930.

was the dentist's ampule. If the physician had obtained adequate instruction in his college course or practical training during

ryngeal obstructions, or the obese, when a safer method is available?

Should patients be subjected to the

FIG. 1. Table set up with essentials for conduction anesthesia. 1, needle $\frac{3}{4}$ inch 25 gauge; 2, $1\frac{1}{2}$ inch 22 gauge; 3, needle 2 inch 22 gauge; 4, needle $2\frac{1}{2}$ inch 22 gauge; 5, needle 3 inch 22 gauge; 6, needle 4 inch 22 gauge; 7, needle 5 inch 22 gauge; 8, needle 6 inch 22 gauge. 9, 10 and 11, 100 c.c., 50 c.c., and 25 c.c. ampules of novocaine solution. 12, Pitkin continuous flow syringe. 13, Iodine solution. 14, Alcohol. 15, Gloves. 16, Gauze and sponge holder.

his internship, he would not have regarded the technic as being highly specialized, but instead would have been familiar with its relative simplicity.

We are obligated to our patients by virtue of their confidence in us to resort to every known means to protect their lives to the best of our ability. Are we worthy of that confidence when we deliberately expose them to the possibilities of ether pneumonia, lung abscesses, shock and gas distention, ileus or acute dilatation of the heart or stomach? Are we adhering to the implied law when we give any form of inhalation narcosis to a cardiac, nephritic, drug addict, alcoholic or asthmatic patient, to those suffering with eclampsia, diabetes, hypertension, arteriosclerosis, decompensation of the heart, pleurisy, pha-

many dangers of inhalation narcosis? Should they be compelled to bear the added financial burden of general anesthesia? Should they be hospitalized or compelled to remain in bed following ether anesthesia? Should tubercular patients be subjected to the possibilities of a fatal pneumonia, or should the profession at large familiarize themselves with a safer, more effectual and more economical form of anesthesia than the ether cone?

The technic of conduction anesthesia has been so simplified, so modernized and the anesthetic solution so safely prepared that there would seem to be no possible excuse for using ether anesthesia in minor surgery. Conduction anesthesia enjoys undisputed advantages over

other forms of analgesia or general narcosis, in that the patient does not have to be prepared before administration. In fact

their preanesthetic state. It is more economical than any form of inhalation anesthesia. This resolves itself into only one

FIG. 2. Upper left: Sharp needle does not tear or traumatize tissues. Upper center: dull needle forced into body causes mutilation and trauma of tissues. Upper right: needle point has been bent. When it is withdrawn tissues are torn. A short beveled needle (A) may be glided over bony surfaces. If the point (B) catches in the bone it will not break. The long beveled needle (C) may cut or penetrate the periosteum, or the point may become bent (D, E) or broken (F). The short beveled needle (G) is preferable for deep injections, to the long beveled needle (H).

it is better to give the anesthetic after a hearty meal. There is no postoperative gastrointestinal disturbance. It eliminates the dread of general anesthesia. Many patients fear the anesthesia more than they do the operation. Shock is not increased by its use; by adding ephedrine shock may be more or less overcome. Arrested tubercular cases are not converted into active ones. Active cases are not subjected to the dangers of fatal lung complications. It may be administered to asthmatics, nephritics, and those suffering with heart lesions, without altering

logical conclusion that the physician or surgeon who in this day and age is not prepared to give certain patients conduction anesthesia is inefficient to the extent of denying his patients something to which they are justly entitled, namely the safest anesthetic.

The advantages of conduction analgesia are many and those of the profession who are familiar with its use look upon it as the safest form of anesthesia we possess for all major or minor surgical procedures with a possible exception of local.

The operator may administer it himself,

a distinct advantage to the country physician, to the industrial surgeon and in emergency cases.

FIG. 3. Intradermal wheal is made with a 25-27 gauge needle (A). Subdermal wheal (A) is raised by causing needle point to penetrate skin from within. Subcutaneous wheal is produced by injecting anesthetic solution in tissues close to skin (needle B). By projecting novocaine solution ahead of needle C, injection is not painful. Injecting solution so that it anesthetizes tissues at side of needle D does not eliminate pain. Pain is produced when needle E is inserted into tissues.

It is more economical to the surgeon, because expensive and cumbersome apparatus is unnecessary; to the patient, as the anesthetist's fee may be saved.

It permits cooperation of the patient, a marked advantage when one is working without assistants in the home or office.

There is no paralysis of the anesthetized field. The patient is able to move, turn or adjust his position to help the surgeon in his work.

Convalescence is shortened and in many cases the patient may be permitted to go home at once. Hospitalization is unnecessary.

The anatomy is not distorted as with local anesthesia. There is no edema of the operative field. The possibility of secondary hemorrhage is lessened. It may be used to anesthetize infected or inflamed fields without fear of contaminating healthy tissues.

Postanesthetic nausea, vomiting, distention or suppression is seldom observed.

No postanesthetic complications follow its use as pneumonia, bronchitis, lung abscesses, etc. Therefore, it is more desirable for the emaciated or aged patient.

It may be administered to patients with inflammatory lesions of the respiratory tract without fear.

Patients do not have to be prepared for the anesthetic.

Conduction anesthesia blocks all afferent nerves. Painful impulses are not transmitted, result no shock.

For fractures and dislocations one experiences a greater relaxation than with any other anesthesia, with the possible exception of deep ether narcosis.

With its use patients suffer less post-operative pain.

It produces no change in the blood chemistry or metabolic rate.

It does not produce or increase diacetic acid or acetone in the urine. Acidosis does not have to be combated.

It is safer than general anesthesia when deep prolonged anesthesia is necessary. Morbidity is eliminated.

The primary and secondary anesthetic mortality becomes nil.

The duration of anesthesia may be regulated according to the amount of the vasoconstrictor agent.

Regular diet may be given at once.

The contraindications of conduction anesthesia are few and as one becomes more familiar with the technic the contraindications become less and less. Children under the age of ten or twelve years might be looked upon as undesirable subjects, but it is remarkable what can be accomplished with these little patients if one will have a little patience. A bottle for infants and candy or toys for the older children will so deviate the attention of the child that the operative procedure may be carried out without interference.

Syphilitics, epileptics, insane or neurotic subjects are looked upon as undesirable for this form of anesthesia. It produces no ill-effect in a luetic, and we never make exception to these cases. We do invariably

eliminate the epileptics, not because we have reason to believe that the anesthetic would in any way affect the patient, but strictly to a few general technical rules. Gain the patient's confidence, promise that you will not hurt him and then keep

FIG. 4. Needle being guided around frontal bone by finger tips of left hand. Insert shows method of anesthetizing entire frontal region from primary central wheal.

because we are fearful of a convulsion during the operation.

Conduction and spinal have been the anesthetics of choice in the State Hospital at Greystone Park for the past two years. The results have been very gratifying. If the neurotic patient cannot be controlled by the preliminary use of morphine and scopolamine, or if there is reason to believe that due to their nervous state they will attribute their future real or imaginary ailments to the anesthetic it will be advisable to use inhalation narcosis.

To experience the gratifying results that are possible in surgery with this form of anesthesia one should adhere

your word. Patients once hurt may not only lose confidence in the method but the doctor. A patient who is subjected to one painful manipulation becomes over-apprehensive to all following procedures. A confidence once lost is hard to regain and may be the direct cause of an unsuccessful anesthesia.

Conduction anesthesia demands a simplified, thorough and skillful technic. When due consideration is given to the minute details the operator will be satisfied and the patient grateful. A knowledge of the anatomic parts, bony landmarks, location of nerves, deep and cutaneous, is essential. Some idea of the anatomical

relations may be had from the accompanying illustrations.

Strict surgical aseptic technic must be

advancing the thumb in the plunger ring faster than the point of the needle travels.

To obtain the desired results with con-

observed. To avoid pain never insert a needle into the tissues unless it is attached to the syringe. Always endeavor to project the anesthetic solution ahead of the needle (Fig. 3, c). This is easily accomplished by

duction or local anesthesia it is essential to have proper syringes, needles and a dependable anesthetic solution of known strength. If one is to use any old syringe or a needle of a large calibre that is rusted

or dull, or a solution that is not stable or discolored, the strength of which is questionable, and the amount of vasoconstrictor sterilized by boiling, because the piston and barrel have the same coefficient to heat.

FIG. 6. Method of anesthetizing infra-orbital nerve. Insert shows nerve distribution, shaded region represents field of anesthesia.

agent uncertain, the results will be so unsatisfactory that in all probability a good method will be abandoned before the technic is mastered. Therefore, I would suggest:

A syringe similar to the author's, a continuous flow instrument, which will permit the injection of the anesthetic agent without detaching it from the needle.

It does not have to be dismantled to be

It contains no unsanitary packing washers or threads.

It is equipped with a locking device that prevents the needle from "blowing off."

The construction is such that there are no working parts to get out of order, with the exception of a small inexpensive rubber valve.

The plunger and barrel are accurately ground which prevents leaking and elimi-

nates sticking of the piston or breaking of the barrel. tip end of the syringe. This prevents the possibility of "pushing off" the end of the syringe.

It is so constructed that it may be

FIG. 7. To anesthetize mental nerve one should endeavor to visualize location of needle point. Foramen is usually found midway between alveolar processes and lower border of jaw, over apex of second bicuspid. Shaded portion of insert shows field of anesthesia.

easily used with one hand, a 5 c.c. capacity accurately graduated. It is equipped with comfortable finger rings that do not cut or hurt the hand.

There is a metal collar on the piston stem that permits the piston to approximate but not come in contact with the

It is so constructed that it may be refilled by withdrawing the plunger. A small valve at the side of the piston stem controls the flow, and as the piston is advanced the solution is injected into the tissues. It is worked not unlike a pump. Should the tip of the needle be within a

vein when the piston is withdrawn blood will appear in the barrel of the syringe which warns the operator that the needle

The needles are the result of three years' alloy experimentation. They will not rust or corrode.

FIG. 8. Anesthetizing mental, lingual, buccal, auriculotemporal and deep temporal nerves by injecting zygomatic fossa. Inset A indicates (1) where needle approaches wing of sphenoid in close apposition to (3) lingual, (4) mental nerves, as they emerge from foramen ovale. Inset B: looking into zygomatic fossa from below, (1) sphenoid plate, (2) foramen ovale.

point is in a vein and the injection should not be made.

It permits of the injection of large amounts of solution in a comparatively short time without removing the needle from the tissues or detaching the syringe.

They are not affected by iodine or ordinary acids.

They are very tough, and will withstand a great deal of bending and manipulation before they will break.

They are equipped with a safety guard,

which prevents them from becoming lost in the tissues should they be accidentally broken.

The temper is sufficient to maintain a sharp point for a long time.

Their flexibility is such that they may

FIG. 9. Ten c.c. of a 1 per cent novocaine solution has been injected under posterior border of sternocleidomastoid muscle, to anesthetize branches of superficial cervical plexus. Cutaneous field of anesthesia is shown in insert.

They may be sterilized for emergency work in a flame. Apparently they have all of the advantages of a platinum instrument at the cost of a steel needle.

be guided in the tissues or around a limb without fear of breaking, and due to this flexible feature large fields may be anesthetized through one puncture wound.

It eliminates the necessity of making a human pin cushion of a patient.

It is inadvisable to use the ordinary

with a bone it may be bent (Fig. 2), and when it is withdrawn tear the tissues, or the tip may be broken and remain as a foreign

steel or nickeloid needle for conduction anesthesia because side pressure cannot be applied without fear of breakage. They become hard and brittle with frequent boilings and break easily. Steel needles rust and corrode. It is as painful to inject a rusty needle as it is to pass a rusty sound into the urethra. Nickeloid needles are not hard enough to maintain a sharp point. They are so brittle that a larger gauge wire is necessary to assure strength.

The wire of a needle should be as small as possible for the particular use to which it is to be adopted. It is never advisable to use a needle larger than a 22 gauge. Large needles or dull needles so traumatize the tissues that they produce pain not only at the time of insertion, but painful sensations due to the injury of the tissues sometimes last for several days. It is inadvisable to use a long-bevel needle for deep injections because if the point comes in contact

body. A short-bevel needle may be glided over or around a bone with ease.

It is advisable to use a needle with a short bevel for deep injections because the point will not bend or break should it come in contact with a bone. If the angle of approach is sufficiently acute the rear of the bevel will make contact with the bone, which permits gliding over the periosteum without tearing or penetrating it. A short-beveled instrument may be controlled and guided in the tissues with greater ease. There is less danger of the point bending or breaking. Should the point of the needle break one will find it is a very difficult task to find and remove the foreign body.

It is always advisable to test the needles before they are sterilized. The longer needles are grasped at the hub between the thumb and finger and the point held in the same manner with the other hand,

and thus bent into a semicircle. The shorter needles are tested by placing the point against the thumb nail and applying

cannot be expected with a preparation of this nature. In the past it has been rather difficult to prepare large amounts of

FIG. 111. Due to difference in contour of a forearm primary wheal is raised laterally and needle A is carried around anterior surface of arm; while needle B is guided by finger tips through subcutaneous tissue to meet end of subcutaneous wheal produced by needle A. Deep nerves are easily anesthetized from central point of introduction on anterior surface of arm.

a moderate amount of lateral pressure. If they are defective it is better to have them break at this time than in the tissues of the patient.

The anesthetic solution should be sterile, staple, and water white, containing a known percentage of novocaine and a definite amount of the vasoconstrictor agent to maintain anesthesia for a definite time. Pink or brownish solutions should not be used. The pink color indicates that the adrenalin is oxidizing, the yellow or brownish solution signifies either that the vasoconstrictor agent has become oxidized, that the solution is stale, or has been oversterilized. The desired results

novocaine solution in the home or office from the crystals, and if one required 100 c.c. of a 1 per cent novocaine solution it would necessitate approximately one hour's time to prepare it, due to the fact that the normal saline would have to be sterilized, the novocaine weighed, and dissolved in the saline, resterilized, cooled and then the vasoconstrictor agent added. This inconvenience and the consumption of time of a busy physician may explain to a great extent why this form of anesthesia is not more generally used in the home or office. One can readily see how impractical its use would be in the home.

To overcome this inconvenience and

place at the disposal of the profession a sterile, staple solution, ready for instantaneous use, the author has had

ephedrine ampules are prepared for use in patients suffering from a hypothyroid condition, as it must be remembered

FIG. 12. Should it be impossible to guide needles A and A' around leg, subdermal wheals are raised and needles B and B' complete wheal. Deep nerves are anesthetized by needles C and D.

prepared ampules of 25, 50 and 100 c.c. capacity with the following formulae:

1. Novocaine 1 gm.
Isotonic solvent 100 c.c.
2. Novocaine 1 gm.
Suprarenin .0005 mg.
Isotonic solvent 100 c.c.
3. Novocaine 1 gm.
Ephedrine .050 mg.
Isotonic solvent 100 c.c.

These ampules are sterilized by emersion in alcohol. The neck is broken and the sinker of the continuous flow syringe inserted into the solution. No other container is necessary. The plain novocaine preparation is sufficient only for anesthesia of short duration. The solution containing the suprarenin will maintain satisfactory anesthesia for two to three hours. The

that these patients cannot tolerate adrenalin or any of its derivatives. To be on the safe side any patient with a pulse rate of over 110 should have the ephedrine solution in preference to the one containing suprarenin, to avoid the possible convulsions that may follow the injection of the synthetic adrenalin preparation into a hyperthyroid patient.

If too great a concentration of suprarenin or adrenalin is used the tissues will be tender and possibly inflamed for two or three days after its use. The patient may complain of a headache and blame his condition upon the anesthetic. It is not an infrequent occurrence to have a patient inform you that they cannot tolerate novocaine as it poisons their system. This

idea is perhaps derived from the dentist's local anesthesia, as they invariably use 1:50,000 adrenalin concentration, some-

will not hurt him. Now let's keep our word. Attach a 25 gauge $\frac{3}{4}$ inch needle to the syringe, expel the air from the

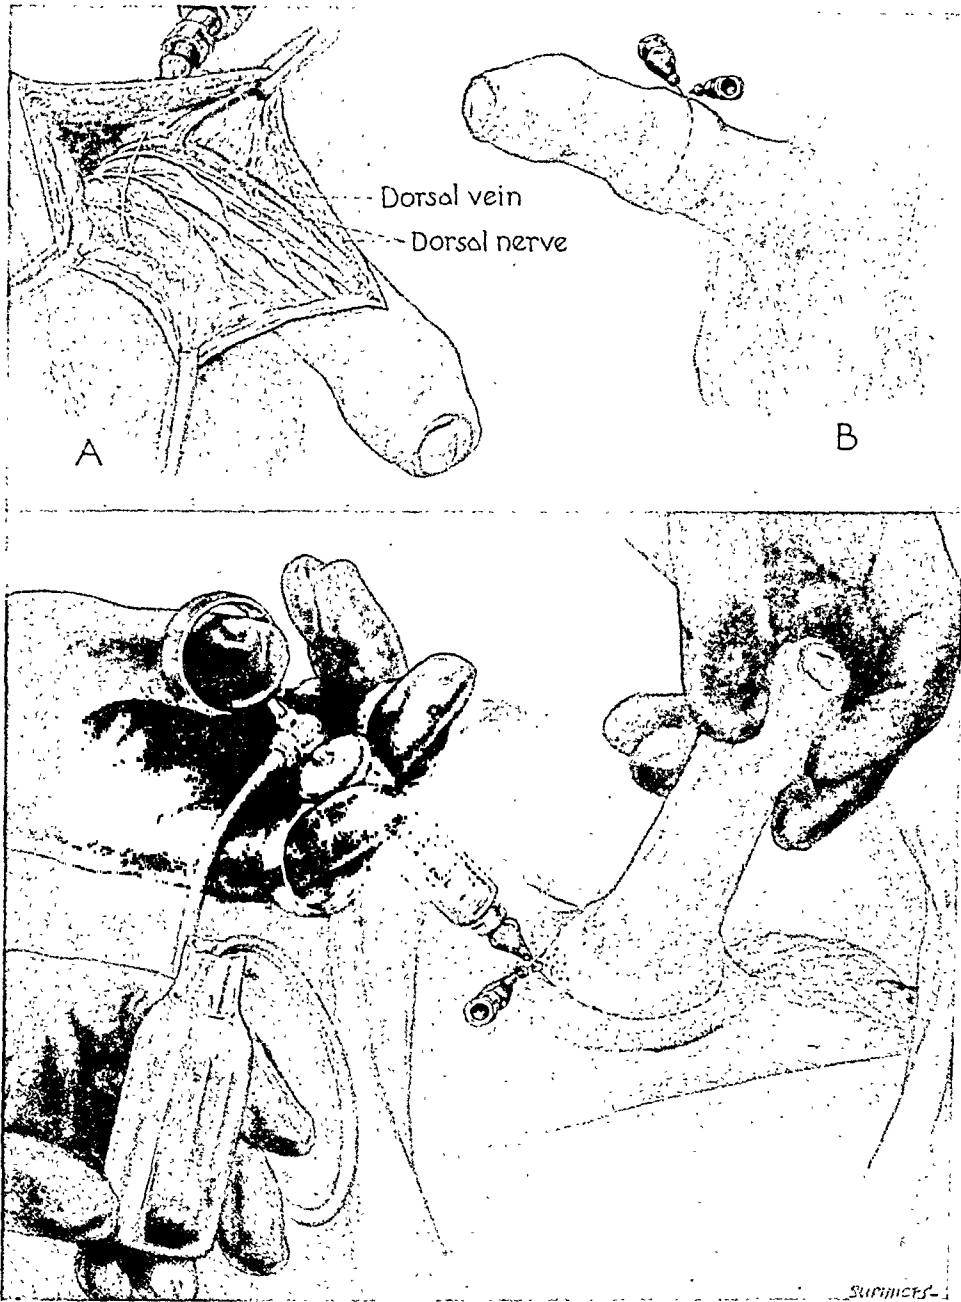

Fig. 13. Method of inserting curved needle around base of penis. Inset A shows needle passing over dorsal vein in close apposition to branches of dorsal nerve. Inset B illustrates method of producing anesthesia for circumcision.

times 1:25,000, and we all know the headache and soreness of the gums that follow its use. The solution already described is a 1:500,000 suprarenin concentration and will not leave any after-effects.

We have promised the patient that we

syringe and supply tube by slowly working the piston back and forth. At the site of the initial injection raise a wheal (Fig. 3 A) the size of your finger nail. The syringe and needle are held at an angle of approximately 20° to the skin. With the point

of the needle lying at the site of the intended wheal, with the skin grasped between the thumb and finger of the left

the original wheal (Fig. 3 D) by the use of 4, 5 or 6 inch needles. If these are to be continued over a greater distance than

FIG. 14. Operator's fingers are placed in palm of patient's hand to prevent needles penetrating palmar skin.

hand, or stretched in the opposite direction by the fingers of the left hand the needle is then introduced with a short, quick, thrust until the bevel has disappeared. Slowly inject a few drops of the solution between the layers of the skin until the wheal of the desired size is raised. If the point of the needle penetrates the true skin the typical wheal cannot be made as the solution is deposited into the subcutaneous tissues. The wheal may be made with little or no pain and anesthesia is produced instantaneously. It is rarely ever necessary to raise more than one intradermal wheal for a field. Should subsequent wheals be desired raise them subdermally (Fig. 3 A). Never attempt to produce an intradermal wheal on the plantar surface of the feet, the palmar side of the hand, or the scalp. Subcutaneous wheals may be made several inches from

the length of the needle a subdermal wheal may be raised by pressing the skin with the finger in advance of the needle point, thus causing the point of the needle to penetrate the skin from within. (Fig. 3 A). The flexible needles advocated will permit one to carry the subcutaneous wheal about the arm or leg from the site of the initial insertion (Fig. 3 B), thus anesthetizing all of the subcutaneous nerves in the region. Two to 4 c.c. of solution should be injected for each inch infiltrated, the amount depending upon the region of the body and thickness of the fatty tissues. Satisfactory anesthesia may be obtained with much less solution in thin individuals.

After the wheal has been made never insert a needle for deep injections unless it is attached to the syringe (Fig. 3 E) as this is an extremely painful manipulation.

When a needle is introduced into the tissues project the solution ahead of the needle as it advances (Fig. 3 c). This

bony landmarks. When nerves are located in the soft tissues and one does not have definite landmarks as a guide, satisfactory

FIG. 15. Cross section of hand showing manner in which needles are introduced between metacarpal bones. Solution is projected through needles as they advance. Needle is then withdrawn to skin surface and reintroduced at an angle that would approach palmar surface, at same point that needle used to anesthetize previous interosseous space stopped.

procedure will not cause pain. Do not insert the needle and inject the solution in such a manner that it will infiltrate the tissues about the side of the needle as this will not eliminate painful sensations.

The superficial or cutaneous nerves are anesthetized with comparative ease. When definite cutaneous regions are to be made insensible to pain it is of course essential to be familiar with nerve supply, and one should know where and how to approach the supplying nerve trunks. To anesthetize the deep nerves satisfactorily an accurate knowledge of their location is required. The operator should not only be familiar with the exact location of the nerve trunks, but he should have a knowledge of their relationship to definite

results may be expected only with practice and experience.

One must bear in mind that the intensity and time required for complete anesthesia of a region will depend upon the skill and training of the physician, the size of the nerve trunk and the quantity and strength of the anesthetic solution injected. One should endeavor to so perfect his technic that satisfactory anesthesia may be secured with relatively small amounts of solution rather than use large quantities. If the tissues of the arm or leg are infiltrated sufficiently anesthesia of course will occur in the distal parts, but this again is approaching local anesthesia, which we are desirous of avoiding. It is our object to anesthetize the afferent

nerves and this may be best accomplished by injecting the solution as near the nerve trunk as possible.

the anesthesia, but relieves the psychic reaction.

The space allotted to this article will

FIG. 16. Anesthetic solution is deposited close to bone. Location of anterior and posterior nerves should be kept in mind and a greater amount of solution deposited about location of nerves.

Ordinarily a 1 per cent novocaine solution is sufficient for most anesthetics. Large nerve trunks or those situated deep within the tissues may be more quickly anesthetized with a 2 per cent preparation. Usually satisfactory anesthesia of the smaller nerves occurs within five to seven minutes if the proper technic has been employed. Should there be no anesthesia after ten to fifteen minutes a second injection may be made without fear. The patient will rarely if ever require any premedication for the ordinary minor surgical procedure. The fears of a nervous individual may be allayed by a preliminary hypodermic of morphine sulphate 0.016 mg. and scopolamine 0.0004 mg. This does not intensify

not permit a complete and accurate anatomical description of the nerve supply, neither will it suffice to describe the minute details of technic as completely as the author desires. Therefore, we must rely upon illustrations to help us exemplify the technical procedures. It has been said that one illustration will convey as much knowledge as 500 words of text. This being so, we may be able to convey our ideas by using a sufficient number of drawings.

The frontal and temporal frontal region of the scalp from the orbital eminence to the vertex is supplied by the frontal, supraorbital, zygomatic, temporal and the auricular temporal nerves, all branches of the trigeminal. These are easily anesthet-

ized by raising a wheal midway between the superciliary arcs. Then attach a 5 or 6 inch 22 gauge flexible needle to the syringe.

FIG. 17. Cross section of finger illustrating location of nerves, relation of needles to bone and nerves. Original contour of finger is preserved by transparency.

The needle is introduced through the center of the wheal at right angles to the skin until the periosteum is felt. Two to 3 c.c. of the anesthetic solution are injected. The needle and the syringe are then carried to the side so that the shaft of the needle lies in close apposition to the skin surface pointing toward the upper part of the ear of the side to be anesthetized. The needle is then rotated so that the arrow on the hub is upward toward the vertex. This would indicate that the bevel is pointing toward the patient's face. As the needle is advanced 1 to 1.5 c.c. of solution is projected into the tissues for each centimeter of tissue penetrated. This produces an edema of the tissues and causes the skin to become elevated, increasing the depth of the subcutaneous space. The needle is easily guided through the edematous tissue with the finger tips of the left

hand (Fig. 4). Fifteen to 20 c.c. of solution will produce satisfactory anesthesia in the adult. Should anesthesia of the entire frontal region be desired withdraw the needle point to the skin surface. It is then pointed in the opposite direction (inset, Fig. 4) when the operator proceeds as before. Should one be fortunate enough to be ambidextrous this procedure is relatively simple. It is unnecessary to do a field block of the frontal region making several punctures of the scalp completely about the region to be operated upon, as all of the afferent nerves of the entire frontal region are completely anesthetized from the one central point. This method affords satisfactory anesthesia for the removal of sebaceous cysts, birth marks, or suturing the scalp. If the nerves have been cut or torn at the time the laceration was produced the skin surface distally has no painful sensations. Should the nerves be intact they are anesthetized, again demonstrating that it is not necessary to surround the lesion with a field of novocaine solution.

The occipitoparietal and posterior temporal regions are supplied by the greater and lesser occipital and posterior auricular nerves. The great occipital is a branch of the second cervical; the lesser occipital and posterior auricular are branches of the second and third cervicals. To anesthetize these a 25 gauge needle is attached to the syringe and inserted through the scalp down to the bone over the external occipital protuberance. Inject 2 to 3 c.c. of a 1 per cent novocaine solution, which raises a subcutaneous wheal, then attach a 6 inch needle, introduce this through the subcutaneous wheal, carry it to the side so that the shaft of the needle approaches the scalp surface, pointing towards the upper portion of the ear, and project the novocaine solution, 1 c.c. for each centimeter of tissue penetrated. The needle is guided around the skull (Fig. 5) by the finger tips of the opposite hand. Should the needle penetrate the pericranium and be caught in the bone it is slightly withdrawn and advanced with less pressure by

the finger tips. Should the needle begin to penetrate the scalp more solution is injected to produce a greater edema, which

Patients rarely if ever complain of any pain with this form of anesthesia, but occasionally where a Martell trephine

FIG. 18. Method of anesthetizing tissues about first metatarsal bone for bunion operation. Note position of operator's fingers on sole of foot. Insert shows relation of needle points to plantar nerves, as needle approaches sole of foot.

will elevate the scalp from the cranium and increase the thickness of the fascia. It is then slightly withdrawn and guided along the superior linea nuchae as before until the subcutaneous wheal extends from the occipital protuberance to the ear (Fig. 5). When anesthesia is desired of both sides of the occipital and the right and left temporal parietal regions the needle point is withdrawn to, but not from the skin surface. It is then carried to the opposite side and the injection made as before. This suffices to anesthetize the occipitoparietal and posterior temporal regions for any minor surgical procedure that may be required.

By using two primary sites of injection (Figs. 4, 5) the entire skin fascia, pericranium and cranium may be anesthetized, which will suffice for major operative procedures on or within the cranium.

is used they will mention that they feel a sensation of heat, which would indicate that thermal sensations have not been entirely obliterated.

Minor surgical operations may be performed upon the lower lid, the anterior portion of the face adjacent to the nose, the alae of the nose or the upper lip by anesthetizing the infraorbital nerve. Lip operations invariably necessitate the injection of both right and left infraorbital foraminae. The needle is introduced through a wheal in the cheek directly below the pupil about 2 cm. below the orbital margin. Ordinarily the foramen may be palpated through the cheek. If this is possible the procedure is much more easily carried out. If it is impossible to palpate the foramen accurately the needle should be inserted through the wheal until it reaches bone, and 1 c.c. of the solution

injected. The syringe and needle then should be adjusted so that the point of the needle will be directed towards the needle that is used to raise the wheal may be carried into the tissues for this injection; the foramen should be searched

FIG. 19. Cross section of foot showing method of inserting needles through interosseous spaces. Needles are again withdrawn to skin surface and reintroduced, fan-like. Six to 8 c.c. of a 1 per cent novocaine solution are introduced into each interosseous space.

pupil and the supraorbital notch (Fig. 6), with the arrow on the needle facing the operator, then the bevel is directed towards the bone. This will permit the needle's gliding over the bone with ease. The barrel of the syringe should then be over the mental foramen or the second bicuspid. By gently moving the point of the needle upward toward the orbit it will glide into the foramen. The bony wall of the canal will prevent the needle from progressing farther, at which time 1 to 2 c.c. of a 1 per cent novocaine suprarenin solution is injected. The $\frac{3}{4}$ inch 25 gauge

for with gentle manipulations to avoid pain or the possibility of a broken needle.

This procedure may be also used for injecting the infraorbital nerve with alcohol for localized facial neuralgia. The alcohol solution should not be introduced into the nerve tissue until complete anesthesia has been secured.

Operations on the lower lip, chin, the lower jaw, the incisor teeth or bicuspid may be performed without pain by blocking the mental nerve, which is accomplished by raising a wheal midway between the angle of the mouth and the lower

margin of the mandible, directly over to the apex of the second bicuspid. The needle is then directed downward and

patient opens and closes the mouth the condyle and coronoid processes may be palpated, which will assist materially

FIG. 20. For removal of toe nail or other operative procedures on great toe anesthesia is produced by depositing 4 to 6 c.c. of a 1 per cent novocaine solution about its base.

forward and advanced until bone is encountered. Inject 1 c.c. of the anesthetic solution before the mental foramen is searched for. This should be found opposite the apex of the second bicuspid midway between the alveolar process and the lower border of the jaw. With the bevel of the needle directed toward the bone it glides into the foramen with comparative ease (Fig. 7). Inject 0.5 to 0.75 c.c. of solution, rotate the needle one-half turn upon its own axis and gently force it deeper into the canal, and inject an equal amount of the anesthetic solution. This will almost instantaneously anesthetize the mental nerve, and the solution that is forced into the canal also produces anesthesia of the nerves supplying the incisor cuspids and bicuspid teeth, also the jaw bone from the bicuspids to the midline.

Operative procedures may also be carried out upon the entire mandible, the lower lip, the tongue or the floor of the mouth by raising a wheal on the skin surface below the inferior border of the zygomatic processes over the sigmoid notch. As the

in locating the sigmoid notch of the ascending ramus. Attach a 2 inch needle to the syringe, insert this at right angles to the skin surface through the center of the wheal previously raised. As the needle is advanced through the skin, connective tissue and masseter muscle, the anesthetic solution should be projected ahead of the needle point. The needle is advanced until the bony resistance of the great wing of the sphenoid is encountered, when 7 to 10 c.c. of solution are slowly injected into the zygomatic fossa (Fig. 8). This bathes the mental, lingual, zygomatic and anterior auricular nerves as they emerge from the foramen ovale. When an operative procedure is to be carried out on the tongue, the floor of the mouth, the anterior portion of the mandible, to the midline of the chin, it is essential that both sides be injected. This procedure is advantageous for the reduction of a dislocated jaw.

It is important that the needle be introduced at right angles to the skin surface to avoid the possibility of the needle

entering the foramen ovale. Should this amount of solution be injected into the extradural space of the middle fossa alarming symptoms might arise. With the proper technic the needle is prevented from advancing farther when the great wing of the sphenoid is encountered.

Anesthesia of the lobe of the ear, the cutaneous and subcutaneous tissues over the mastoid region, the lateral and anterior portions of the neck from the angle of the jaw to the clavicle may be obtained by having the patient rotate the head in the opposite direction from the side to be anesthetized. This will bring into prominence the sternocleidomastoid muscle. Raise a wheal over the posterior border of the muscle midway between the tip of the mastoid and the clavicle; then insert the needle directly inward toward the transverse processes of the cervical vertebrae, for $\frac{1}{2}$ to $\frac{3}{4}$ inch, depending upon the thickness of the subcutaneous tissue, and inject 10 c.c. of a 1 per cent novocaine solution. There is little or no danger of penetrating the carotid artery or jugular vein, as these lie well in under the muscle. The point of the needle with the proper technic would be at least $\frac{3}{4}$ inch from the vessels (Fig. 9). This will anesthetize the occipitalis minor, posterior auricular, superficial cervical, spinal accessory, acromial, outer, middle and internal clavicular, and the suprasternal nerves, which constitute the superficial cervical plexus.

The anesthesia produced is sufficient for any superficial operative procedure on the neck from the lower margin of the jaw to the clavicle. The external ear is completely anesthetized. There is cutaneous anesthesia over the acromial region, and 3 or 4 inches below the clavicle. Superficial cervical glands may be removed with this anesthesia, provided they are not too close to the borders of the jaw, when it becomes necessary to infiltrate along the border of the mandible. This form of anesthesia is preferable to local infiltration for thyroidectomies, but here we are overstepping the bounds of minor surgery.

For the reduction of fractures or dislocations of the hip or femur spinal anesthesia is the anesthetic of choice, but for the arm or leg, conduction anesthesia gives us many undisputed advantages over any form of inhalation narcosis, in that:

We are able to obtain greater relaxation than with any form of anesthesia with the possible exception of deep ether narcosis.

It permits reduction under the fluoroscope without fear of spark explosions, and the operator's work is not hindered or embarrassed by a cumbersome gas-oxygen machine.

The patient is conscious and able to assist in the reduction of a fracture or dislocation.

It does not necessitate the hospitalization of patients. They may be permitted to go home as soon as the splints or caste is applied.

The anesthesia lasts sufficiently long to benumb the parts several hours after reduction. To attempt to describe a technic for all possible fractures that one might encounter would be quite impossible in this short article.

For fractures of the humerus, ulna and radius, or dislocations of the elbow, brachial anesthesia would be preferable, but unfortunately the technic is such that it is not readily understood by all practicing physicians. Therefore, an endeavor will be made to describe methods of anesthetizing parts at or above the site of fracture.

An over-riding fracture of the lower third of the humerus may be reduced by inserting the needle A (Fig. 10) through the wheal raised over the center of the biceps approximately 2 inches above the site of the fracture. This is carried around the arm in the subcutaneous tissue until the point is over the center of the triceps, 1 c.c. of solution being projected ahead of the needle for each centimeter of tissue traversed. The needle is guided by the finger tips of the left hand. The needle point is then withdrawn to the skin

surface and reintroduced in a similar manner as shown by B (Fig. 10). This raises a subcutaneous wheal that anesthetizes all of the cutaneous nerves. Should one find difficulty in introducing the needles A and B and guiding them around the arm, the same results may be obtained in anesthetizing the cutaneous nerves as shown in Fig. 12 with needles A and A' the points of which raise a subdermal wheal through which needles B and B' are inserted to complete the circular subcutaneous wheal. At the inner border of the biceps needle C is introduced and directed toward the posterior surface of the humerus, projecting the solution as the needle advances. When it has been inserted into the tissues 1.5 cm., 5 c.c. of solution are injected. It is then inserted in the same axis another centimeter and 5 to 10 c.c. of solution are injected. This anesthetizes the cutaneous, antibrachial and the ulnar nerves. The needle point is withdrawn to the skin surface and inserted toward the anterior surface of the humerus, and as it advances 10 to 15 c.c. of solution are injected into the tissues, to anesthetize the median and musculocutaneous nerves. The needle is then withdrawn and inserted through the skin at the outer border of the biceps directly towards the center of the humerus, until its progress is stopped by the bone. Inject 10 c.c. of solution. Withdraw the needle E to the skin surface and reintroduce it to the posterior part of the humerus; again inject 10 c.c. of the novocaine solution. This anesthetizes the dorsal cutaneous, antibrachial and the radial nerves. This technic suffices only for anesthetizing the radial nerve at the level illustrated, because at a higher level the radial nerve is internal to the humerus, as are the ulnar and median nerves. At a lower level it is external and anterior to the bone.

Ten minutes should elapse before manipulations are attempted, at which time anesthesia should be complete. When a needle is being inserted only very small amounts of the novocaine solution should be injected at a time. As the nerves are

approached by the point of the needle the piston of the syringe should be withdrawn, and if blood does not appear in the barrel of the syringe the injection is made. If blood is observed in the syringe it indicates that the needle tip is within a vessel and it should be slightly withdrawn or inserted deeper before the injection is made. To avoid injecting the solution into a vein after blood is observed in the barrel of the syringe it is advisable to disconnect the syringe from the needle and expel the contents to remove the blood-stained solution. When a blood vessel is penetrated with a small gauge needle little or no harm is done. The edema produced by the subcutaneous wheal disappears by the time anesthesia is complete. One need not hesitate to apply splints or a plaster cast as the case may indicate.

To reduce fractures of the ulna and radius it is advisable to inject the anesthetic solution a couple of inches above the fracture, but should the operator feel that he is not absolutely certain of his nerve relations the injections may be made as shown in Figure 11 by raising a circular subcutaneous wheal about the arm, at the site of the fracture, with needles A and B and injecting 10 to 15 c.c. of a novocaine solution through each of the needles C, D and E, and between the fragments of the bones to anesthetize the radial, medial, ulna and interosseous nerves as shown in Figure 11, inset. This procedure simulates local anesthesia in that the anesthetic solution is injected directly into the field to be anesthetized. Due to the contour of the forearm it is advisable to raise the primary wheal laterally instead of over the anterior surface as in the upper arm. The subcutaneous wheal is produced by using a 4 inch needle, which is guided through the tissues by the finger tips of the left hand (inset, Fig. 11).

Should the operator feel that he is not absolutely certain of his nerve relations the injections may be made as shown in Figure 11, by raising a circular subcutaneous wheal

with needles A and B, and injecting 10 to 15 c.c. of solution through each of the needles C, D and E, to anesthetize the radial, medial, ulnar and interosseus nerves (inset, Fig. 11).

Until one has become well acquainted with the technic often twice as much solution will be required to produce satisfactory anesthesia, that is instead of using 50 c.c. to anesthetize the forearm, possibly 100 c.c. will be required by one unfamiliar with the technic. One should not hesitate to use a quantity sufficient to produce satisfactory anesthesia.

For a fracture of the lower third of the tibia and fibula a primary intradermal and subcutaneous wheal is made as described in the arm cases. Needle C is introduced external to the tibia and carried backward and outward in such a manner that it will pass over the outer border of the fibula. About 20 to 25 c.c. of novocaine solution are deposited as the needle advances. This will suffice to anesthetize the deep and superficial peroneal nerves. There is little or no danger of penetrating blood vessels in this field. The needle is withdrawn and reinserted through the mid-portion of the soleus muscle. When it has penetrated the tissues 1.5 cm., 10 c.c. of novocaine solution is injected. The needle is then advanced until its progress is stopped by the posterior border of the tibia. When it is withdrawn 1 cm., 10 c.c. of the anesthetic solution is again injected to anesthetize the posterior tibial and medial cutaneous nerves.

To anesthetize the penis for circumcision, ureterotomy, fistula, anterior strictures, plastic operations or amputation, a wheal is raised on the base of the penis below the pubic spine. A $2\frac{1}{2}$ inch needle is bent in a semicircle, similar to a half-curved surgeon's needle. The penis is held in position with the left hand. The needle attached to the syringe is introduced through the wheal and carried down to the corpora cavernosa on the right side. Three to 4 c.c. of novocaine solution are injected (Fig. 13). The needle is then guided around

the penis, projecting 1 c.c. of solution for each centimeter of tissue traversed to the raphe. The needle point is withdrawn to the skin surface. The skin including the wheal is displaced slightly to the left. The needle is reintroduced as before and a subcutaneous wheal made on the left side to the raphe, to meet the wheal produced on the right side. These injections block the dorsal nerves of the penis and their branches (Fig. 13 A). For a simple circumcision satisfactory anesthesia may be secured by raising a wheal on the dorsum of the penis midway between the symphysis and glans, and through this the curved needle is introduced to the right. Five to 6 c.c. of solution are used to produce a subcutaneous wheal on the right side. The needle point is withdrawn to the skin surface and a wheal is produced on the left side in a similar manner (Fig. 13 B).

All operative procedures upon the hands may be performed painlessly by anesthetizing the cutaneous, ulnar, median and radial nerves at the wrist (Fig. 11). If an infection or cellulitis of the hand exists it is preferable to produce the anesthesia well above the infected region in order not to contaminate the healthy tissues. For severed tendons the anesthesia should be produced high enough to enable the operator to dissect out the retracted tendon. When the parts are not infected it is advisable to anesthetize only that part of the hand or fingers upon which the surgical procedure is to be carried out. The fingers may be anesthetized above the metacarpophalangeal articulation. If, for instance, the index finger is to be anesthetized a wheal is raised on a dorsal surface of the hand above the metacarpal articulation. The patient's hand is held by the operator's in such a manner that the surgeon's fingers are in the patient's palm. The thumb of the left hand glides the skin containing the wheal toward the thumb. A 2 inch needle is inserted through the inner border of the wheal, and so adjusted that the bevel faces the

metacarpal bone. It is then passed along the side of the bone slowly injecting the solution as the needle advances. When the point of the needle is felt by the operator's fingers on the palmar surface a subcutaneous wheal is raised with 2 or 3 c.c. of solution. The needle is then withdrawn again slowly injecting the novocaine solution. The patient's skin is pushed outward and the needle is rotated so that the bevel faces the outside of the metacarpal bone. It is again introduced until the tip is felt by the fingers in the palm, injecting 3 or 4 c.c. of solution as the needle proceeds (Fig. 14). Four to 6 c.c. of a 1 per cent novocaine solution should be injected on each side of the metacarpal bone. The needle should never be permitted to penetrate the palmar surface of the hand. If two or more fingers are to be anesthetized a subcutaneous wheal is raised on the back of the hand, and subsequent injections made through this wheal as shown in Figure 15. Five to 7 c.c. of a 1 per cent novocaine solution should be introduced into each interosseous space. After the injection is made the hand should be gently massaged to disseminate the novocaine solution. Anesthesia should extend to the finger tip in five to six minutes. It is inadvisable to attempt any operative procedure until the tip of the finger is completely anesthetized. Twenty-five to 35 c.c. of a 1 per cent novocaine suprarenin solution should be sufficient to anesthetize all of the fingers.

To anesthetize an individual finger a wheal is raised over the base of the first phalanx. The patient's finger is held by the operator as shown in Figure 16. The skin and wheal over the base of the finger are pushed outward by the thumb 2 to 3 c.c. of solution are slowly injected as the needle advances until the tip is felt by the fingers of the operator. The needle is withdrawn, the skin and wheal are retracted inward by the thumb of the operator, and 2 to 3 c.c. of solution are injected in a similar manner on the inner side of the phalanx (Fig. 17). Care should

be taken not to inject too much solution as this may produce a constriction about the finger and impair circulation. If the tissues are too much edematized or if too great a constriction is produced, necrosis of the tissues may be produced. When injections are made around or about a bone the bevel of the needle should be in apposition to the bone. If the point of the needle is directed toward the bone it may penetrate the periosteum or catch in the bone, bend or break the point, or possibly break the needle.

Anesthesia of the feet or toes may be produced with a very similar technic to that of the hands. If an operation for hallux valgus has once been performed with conduction anesthesia I doubt very much if the operator would ever use any other method. The patient is conscious, the motor function is not disturbed and when the operation is completed the operator is enabled to observe the function of the joint.

Raise an interdermal wheal $1\frac{1}{2}$ inch above the metatarsophalangeal articulation. Attach a $2\frac{1}{2}$ inch needle to the syringe. The operator places his fingers under the sole of the foot and the thumb displaces the wheal outward over the first interosseous space. The needle is introduced through the wheal. Five to 7 c.c.s of a 1 per cent novocaine solution are injected as the needle advances to the plantar surface. The needle is withdrawn, the thumb of the operator retracts the wheal to the inner surface of the metatarsal bone. The needle is then inserted to the inner side of the metatarsal bone (Fig. 18) and an equal amount of solution injected. As soon as the solution penetrates the skin it anesthetizes the dorsal cutaneous nerves; the peroneus nerves are encountered opposite the dorsal surface of the metatarsal bone, (Fig. 19); the needles approximate the medial and plantar nerves on the sole of the foot as shown in Fig. 18, inset. If the entire foot is to be anesthetized the technic is similar to that of anesthetizing the hand. The needles are inserted

through the interosseous spaces as shown in Figure 19. The technic for anesthetizing a single toe is as simple as anesthetizing a finger. The great toe, due to its size, necessitates the raising of two wheals internal and external to the tendon (extensor hallucis longus). Two to 3 c.c. of a 1 per cent novocaine solution are injected on each side of the phalanx (Fig. 20).

The other toes may be anesthetized from a single wheal raised on the dorsal surface; 1.5 to 2 c.c. of solution on either side of the bone will be sufficient to produce complete anesthesia.

It is hoped that these suggestions will be of some assistance, in minor surgery, to the isolated practitioner, industrial surgeon and those members of the profession who are not familiar with novocaine anesthesia.

Picture a patient fighting, gagging, coughing, suffocating and cyanotic from inhalation narcosis, as compared to the

patient who is comfortable, at ease, laughing and talking with his doctor doing the operation.

Try and visualize the patient's discomfort for the first twenty-four hours following general anesthesia, as compared with the one that has had all of his fingers amputated with conduction or local anesthesia, who is permitted to go home and eat a hearty meal.

Should a patient be subjected to the possibilities of anesthesia nausea, vomiting, distention, bronchitis, pneumonia, lung abscesses and innumerable other narcosis complications, when they may be avoided? Would you submit to ether anesthesia to have an ingrowing toe nail removed? No. Then why compel a patient to take it.

Why have thousands of physicians adopted local conduction and spinal anesthesia in the last few years in preference to inhalation narcosis? Because it is safer.

THE USE & ABUSE OF ANTISEPTICS*

ZACHARY COPE, F.R.C.S.

LONDON, ENGLAND

THERE is still great variation of opinion as to the value of antiseptics.

The most blind faith appears amongst those chemical manufacturers who send round advertisements showing how easily microbes can be killed by the particular antiseptic they are recommending. The extreme form of scepticism is found among certain laboratory workers who contend that it is the physiological response of the body tissues, and not the antiseptic, which kills the microbe. Between these extremes come the clinicians who vary from the conscientious believer in the efficacy of antiseptics, to the perfunctory user who has little faith in their value. Very few have a discriminating judgment in the matter. This is not to be wondered at since clinical and laboratory evidence often

appear to contradict one another, and principles have been neglected for rule-of-thumb practice. Before trying to estimate the true value of antiseptics, one must cast aside some of the commonly employed untrustworthy criteria. Little reliability can be placed on experiments showing the power of an antiseptic acting in a watery medium, for in the body it has to act in a serous fluid. Nor can one make a true judgment of its effect on microbes in the wound without at the same time allowing for the extent of its deleterious action on the body tissues, the speed with which it acts, and the type of wound to which it is applied.

The contrast between the aseptic and the antiseptic schools is a false one, and the founder of antiseptic surgery fully

* Submitted for publication November 27, 1929.

appreciated the value of both methods. Lister's aim was to produce an aseptic wound by antiseptics, but he quite realized that where infection was minimal, aseptic technic could produce as good results as the antiseptic method. He wrote "These two great truths have been taught us by advancing science, that normal serum is not a good soil for the development of attenuated microbes and that bacteria introduced among the tissues, if in not too concentrated form, are disposed of by phagocytosis." Those who stress the damage done by antiseptics to the tissues are only following the lead of Lister who wrote: "In treating surgical cases antiseptically I always endeavour to avoid the direct action of the antiseptic substance upon the tissues, so far as was consistent in the existing state of knowledge with attaining the essential object of preventing the development of injurious microbes in the parts concerned."

It will serve to clarify our ideas if we consider the subject with reference to the different varieties of wounds which for our purpose may be classed as:

1. Clean.
2. Contaminated.
3. Deeply infected (including nearly all gunshot wounds).
4. Granulating.

A few words may finally be devoted to the action of antiseptics on microbes dwelling on intact surfaces.

1. The clean wound is one made under aseptic conditions by the surgeon, or made accidentally with so little chance of contamination that for practical purposes it may be deemed sterile. Such wounds do not need the application of any antiseptic, though every effort must be made to maintain the aseptic state by seeing that everything which comes in contact with the wound is sterile. Gloves, dressings and suture materials must be sterile.

2. The contaminated wound is one in which pathogenic organisms have been planted on the surface, but have not had

time to grow out into the tissues. Can antiseptics destroy the bacteria in such a wound? If so, for how long after the contamination is such a destruction possible?

Experimental work on this problem is apparently contradictory. On the one hand Fleming¹ made glass tubes with special recesses, and found that microbes planted in the recesses were not killed by antiseptics placed in the tube. On the other hand Carl Browning² and his co-workers experimenting on guinea-pigs found that acriflavine solution applied to a subcutaneous pocket planted with virulent bacilli, always killed the organisms, provided the strength of the solution was as much as 1:1000, and the application was made within two hours of the bacterial implantation. These experiments were controlled. The final judgment in this matter should rest with the clinician, but there are surprisingly few scientifically accurate clinical observations recorded. Fortunately it was in the recently contaminated wound that Lister first demonstrated the value of antiseptics. In his first communication on the subject, Lister recorded 11 cases of compound fracture. In 2 he does not mention how long after the infliction of the wound the application of the antiseptic was made, but in the other 9 cases full details are given. Suppuration occurred only in 2 cases in which the antiseptic was applied respectively four and six hours after the accident. No suppuration occurred in the other cases which were more promptly treated, nor did infection gain a hold in one small wound treated six hours after the injury. We think the results of general clinical work bear out the view supported by Lister's original record and Browning's later experiments, that contaminated wounds treated adequately by antiseptics, within four hours of infliction, do not suppurate. This means that the casualty department should be run on antiseptic lines. We have not space here to discuss the best antiseptic to apply, nor the best

¹ FLEMING, A. *Brit. J. Surg.*, 7: 99, 1919-1920.

² BROWNING. *Brit. M. J.*, 1: 73; 2: 70, 1917.

method of application, but it is important to insist that the dressing to the wound should be large enough and impregnated with sufficient antiseptic to prevent microbes gaining access through the dressing.

3. The next class of wound is the deeply infected wound, i.e. one in which the organisms are no longer confined to the most superficial layer of the wound, but have begun to grow out into the tissues. Generally speaking, if a contaminated wound is untreated it must be regarded as deeply infected after four to eight hours. Of course it will be quite clear that a good deal depends upon the amount and virulence of the initial contamination. Nearly all gunshot wounds must be regarded as deeply infected from the first, since the force of the missile drives any organisms deeply into the tissues. This lesson was only tardily learned in the Great War.

Can antiseptics help in this group? Theoretically the answer must be very doubtful, for antiseptics which are strong enough to kill microbes would also seriously damage the tissues into which they had penetrated. But there are other factors to be considered, for it has been shown that antiseptics cause a flow of serum which is antibacterial to most organisms, though not to the dreaded streptococcus. Fleming found that in the concentrations commonly used for the treatment of wounds, most antiseptics will inhibit the growth of organisms in serum, and even in some cases kill organisms in pus, yet they at the same time retard the emigration of leucocytes, and diminish their phagocytic power. The ultimate effect of an antiseptic is therefore a complex problem. Experimenting with a chronic septic wound, Fleming found that neither the instillation of, or irrigation with an antiseptic had any great influence in diminishing the number of microbes in a wound. We accept Fleming's work as conclusive as regards most of the common antiseptics, and clinical work largely bears out his

conclusions. We all know that septic wounds which are washed out with an antiseptic solution still continue to discharge pus, and any rapid improvement is as likely to be due to the natural resistance of the tissues as to the antiseptic. From this general condemnation, however, we would except the flavine and the hypochlorite groups of antiseptics. Those in the flavine group act very strongly in serum, and Fleming's experiments with them were not so convincing; while the hypochlorites have a very rapid action, cause a considerable flow of serum, and are backed by strong clinical support. In the case of most antiseptics we conclude that their chief benefit, when used to wash out, or apply to a deeply infected wound, is to ensure the sterility of the fluid used and to prevent the introduction of further organisms.

The ordinary antiseptics were proved to be of little value in dealing with gunshot wounds in the early days of the Great War, and it was because of this failure that Sir Almroth Wright sought to encourage the physiological response of the body by applying hypertonic salt solution to wounds. There is no doubt that the application of this solution causes the flow of an albuminous fluid with considerable antibacterial properties, but the leucocytes are repelled by the hypertonic solution. If this method of treatment is adopted normal saline must be applied alternatively with the hypertonic solution, so that leucocytes may be permitted to come into the wound.

The infected track of the majority of gunshot wounds is inaccessible to ordinary antiseptic applications, so that excision of the track is the method of choice when possible. After excision the wound can be treated by the physiological or antiseptic methods, preferably by the antiseptic Carrel-Dakin technic. The stuffing of antiseptic powders or pastes or even salt packs into the narrow track of a gunshot wound has nothing to commend it.

4. In a granulating wound the healthy tissues next the injured part have formed a natural barrier against infection and the rational plan for the surgeon is to do everything he can to protect those delicate granulations. They may be injured by accumulated discharges therefore drainage must be efficient; they may be irritated by foreign bodies which must be removed. They may also be seriously damaged by antiseptics and this fact should prevent the surgeon ever applying strong antiseptics to a granulating wound unless he wishes to destroy exuberant or feeble granulations.

It has been satisfactorily proved that most antiseptics have little or no effect in reducing the number of organisms on the surface of a granulating wound, so that the common routine washing out of healing wounds can have little action but the removal of debris to commend it. The only exception is that of the hypochlorites. Experiments by Parry Morgan on films of pus in vitro and investigations by Fleming on a granulating wound in vivo, show that the hypochlorous solutions are likely to have a definite bactericidal effect on the organisms on the surface of a granulating wound even if used merely as a lotion to wash the surface.

There is no need to wash out the cavity of an ordinary abscess. In relating the treatment of an acute abscess by incision and drainage Lister made the significant remark: "The antiseptic substance was never from first to last applied to the cavity of the abscess as such treatment could only have been productive of needless irritation."

We can summarize our conclusions by saying that all the evidence goes to prove that antiseptics are not needed in clean wounds, but are exceedingly valuable in recently contaminated wounds; while in deeply infected and granulating wounds they have little direct antibacterial action except in the case of the hypochlorites. The success of the Carrel-Dakin technic

bears out clinically what the laboratory asserts.

EFFECT OF ANTISEPTICS ON SKIN AND MUCOUS MEMBRANES

Experimental work shows that it is exceedingly difficult to kill the organisms in the depths of the skin. It is indeed doubtful whether it is possible to sterilize skin without doing too much damage to the normal cells of the part.

This fact should enforce the wearing of sterile gloves for operations. Nevertheless though one may not be able to render the deep parts of the skin absolutely sterile there is good clinical ground for believing that some antiseptic applications are valuable for rendering the surface almost sterile. The use of tincture of iodine, picric acid solution, and some of the aniline dyes has strong clinical support, and the experiments of Lister showing that carbolic acid had a special avidity for hair makes a 1:20 or 1:40 solution suitable for application to the scalp (away from the eyes) the axilla and peri-anal tissues.

Mucous membranes are more delicate than skin and we are not aware of any reliable controlled clinical or experimental work which supports the view that microbes lodged in crypts or recesses can be killed by antiseptics. It may well be that organism which have just been planted on the mucous membrane may be killed by an antiseptic application. This would be parallel to the treatment of a recently contaminated wound and supports the practice of applying a solution of silver nitrate to a conjunctival sac recently infected with the gonococcus. But the washing out of infected mucous cavities with antiseptic solutions has little to support it other than that the antiseptic keeps the fluid sterile.

Unless the principles underlying treatment by antiseptics are understood success can only be accidental. It should be the aim of every practitioner to understand principles so as to ensure success.

DISLOCATIONS OF THE SHOULDER*

EMMET RIXFORD, M.D.

STANFORD UNIVERSITY, CALIF.

FREQUENCY

ABOUT half of all dislocations are of the shoulder, roughly 4 in males to 1 in females, occurring at any age but with increasing relative frequency as age advances.

ANATOMICAL AND PHYSIOLOGICAL CONSIDERATIONS

The fundamental reason for the greater frequency of dislocations of the shoulder joint is that here nature has found mobility more useful than stability.

This great mobility is permitted by the peculiar construction and roominess of the capsule and by the small size of the glenoid cup covering as it does, even when expanded by the cotyloid ligament (labrum glenoidale), only about one-third of the cartilaginous surface of the head of the humerus.

An essay might be written on the question "What keeps the head of the humerus in place?" and this most interesting phenomenon not be adequately explained. Suffice it here to say that the matter is most complex, many forces and many organs taking part in it.

All the muscles connecting the humerus with the scapula, even the greater pectoral, by their tone assist and by active contraction in a sort of reciprocal relation: when one group contracts, its antagonists relax. Of these the most effective in this relation are the deltoid, and supraspinatus and the triceps; witness the ease with which dislocation occurs in poliomyelitic paralysis of these muscles.

The capsule is wonderfully built to permit such free motion as that of the shoulder joint and yet make important, perhaps the largest, contribution to its stability.

Atmospheric pressure is given the major

place by some, but atmospheric pressure can become effective only in case a vacuum is formed in the joint. If such were present it would soon be filled with serum and blood and the pressure would cease, but if any force pulls the head of the humerus away from the glenoid such a vacuum is instantly formed. In other words atmospheric pressure is ready to resist any such motion though it does not maintain pressure otherwise. Atmospheric pressure does not prevent the weight of the arm producing a subluxation in deltoid paralysis.

Much the same can be said of capillarity though it may well be that this force deserves the major position; witness the adhesion of "optically" perfect surfaces anywhere; the lung to the chest wall (Macewen), the lids to the eyeballs, the boy's famous "sucker" to the cobblestone.

CLASSIFICATION

Most classifications of shoulder dislocations are based on the positions in which the head of the humerus comes to rest, secondary positions, but a clear understanding of the etiology and therapy requires knowledge of the primary positions i.e., the positions of the head of the humerus as it leaves the socket and thence the location of the rent in the capsule and other damage done.

Well over 90 per cent of all dislocations of the shoulder are primary subglenoid displacements in front of the triceps tendon.

Primary posterior dislocation is next in frequency but is not common, in fact comprising not over 2 per cent of all dislocations of the shoulder. The head of the humerus may go out between the tendon of the triceps and the teres minor but may be above the latter, coming to rest under the acromion or under the spine of the scapula, generally complicated

* Submitted for publication December 7, 1929.

by tearing off of the subscapular muscle or the lesser tuberosity.

The secondary or final positions of the head of the humerus are many. The principal anterior dislocations are, in order of frequency: subcoracoid, subglenoid and subclavicular and the rare *luxatio erecta*. Posterior dislocations are described as subacromial and subspinous with the rare, even disputed subtricipital dislocation, the result of internal rotation of the shaft with pressure backward, comparable to the reversed anterior dislocation of the hip.

MECHANISM

In the laboratory the humerus may be readily dislocated by a heavy blow struck in a downward direction on the upper part of the abducted arm and posterior dislocation may be produced by forced internal rotation with something of a blow in front. There is no doubt that dislocations as seen clinically are sometimes produced by such blows on the top of the shoulder, as in falls forward or backward, but the great majority occur as the result of leverage, often doubtless with some thrust added.

Abduction of the shoulder is normally limited by tension of the lower portion of the capsule, balanced by compression of contact of the head of the humerus with the glenoid. If abduction be forced beyond the limit something must give way; the surgical neck of the humerus, the neck of the scapula, the greater tuberosity which impinges on the upper border of the glenoid or the capsule of the joint.

The capsule may yield in its continuity or it may be avulsed at its insertion at the edge of the glenoid or at the neck of the humerus. Most commonly it is torn in continuity in its lower portion, perhaps because the curvature of the head of the humerus is greater there than elsewhere. The greater tuberosity comes into contact with the upper edge of the glenoid, to which point, therefore, is instantly trans-

ferred the fulcrum or center of rotation which is normally at the center of the head. The short arm of the lever is thereby lengthened so that further abduction forces the head of the humerus out of the rent in the lower limb of the capsule and lifts its surface away from that of the glenoid. The protrusion is made still greater by the fulcrum being transferred to the acromion or the coraco-acromial ligament, for in further elevation of the arm or further abduction the surgical neck of the humerus comes into contact with the one or the other. Even slight thrust will now serve to throw the head of the humerus completely off the glenoid into the axilla.

This mechanism is that of an exceedingly common accident; people fall forward or sidewise, throw out their arms for protection, the arm, inadequate to overcome the momentum of the body, is forced into exaggerated elevation or abduction. In the former the acromion or coracohumeral ligament becomes the fulcrum, in the latter the greater tuberosity at the edge of the glenoid. But since hyperextension in the sagittal plane ordinarily occurs with the arm in internal rotation, the greater tuberosity is thrown against the edge of the glenoid even in this motion.

When the arm is brought down to the side the head takes its so-called secondary position. Since the majority of falls producing dislocation are forward, the arm is forced backwards, the head is thrown forward and inward, the degree of mesial displacement depending on the force of the longitudinal thrust.

Thrust with the arm in full extension is the cause of the interesting though rare "*luxatio erecta*," in which the arm is held straight up above the head. In a personal case the patient tripped on a rug and fell forward catching her extended arm on a bureau.

It goes without saying that the greater the displacement the greater must have been the laceration of the capsule. In most dislocations the coracohumeral liga-

ment remain intact and like the ilio-femoral ligament determines much in the mechanism not only of production of the secondary positions of the head, but also of reduction. The same is true of the posterior portions of the capsule.

DIAGNOSIS

There should be no difficulty in making a diagnosis of any of the various forms of dislocation, but posterior dislocation was overlooked in the beginning in a considerable proportion of the cases reported and errors of diagnosis from fracture are too common. The loss of the roundness of the shoulder, Dugas' sign in anterior dislocation (inability to depress the elbow when the hand is on the opposite shoulder) positive palpation of the head of the humerus in its abnormal position, finally the x-ray which determines not only the fact of dislocation and the exact position of the head, but also shows complicating fracture if any be present. In dislocation the arm is generally held in elastic tension; in fracture of the surgical neck, mobility of the arm is unrestricted and the roundness of the shoulder persists. Moreover, the head fails to rotate normally with rotation of the shaft.

The careful surgeon will always assure himself, before instituting treatment, that the nerves and blood vessels are intact.

There is great advantage in having x-ray films taken in stereoscopic relation, for when viewed in a proper stereoscope many details can be observed which might otherwise be lost, such as the size and position of small fragments of bone.

TREATMENT

Most dislocations of the shoulder are easily reduced and without anesthetic, if taken while the tissues are still benumbed by the violence of the accident, but the difficulties of reduction increase with the passage of time until after a few weeks, they are so great as to make reduction all but impossible, even under anesthesia, and yet by using great force dislocations have been reduced even after several months.

Rarely dislocation is impossible of reduction from the beginning. Dollinger of Buda-Pesth operated on a considerable number and generally found the subscapularis muscle in the way. Cutting the muscle (and capsule) made reduction simple.

The head of the humerus may pass below and around or through the lower edge of the muscle and lie on its anterior surface, or by reason of thrust, it may pass through or above the muscle, reaching its anterior surface in that way.

The oldest method of reducing dislocation of the shoulder is by lateral traction with or without manipulation of the head. As a definite method it can be traced to Avicenna of the school of Salernum, but it is doubtless far older. It is not only the oldest method, it is really the best. It is efficient in most cases in which reduction can be effected at all, and is without danger. The method naturally has numerous modifications. One of the best is that of Stimson, in which the patient lies on his side on a cot set upon a table or chairs, his arm passed through a hole in the canvas of the cot, a weight tied to his hand. Such continuous traction soon tires the muscles and reduction is readily effected. Hofmeister does the same thing by having the patient lie on his sound side in bed or on the floor, traction being made by a cord attached to the hand of the dislocated arm and passed over a pulley on the ceiling, a gradually increased weight on the other end of the cord.

The essential element of all methods of reduction is to secure muscular relaxation. If one can pull the arm immediately after the accident and before muscular spasm has come on, reduction may be effected without the use of much force. Many a dislocation has been reduced by this means by sympathetic bystanders at the time of the accident.

While the use of great force in refractory cases was justified in pre-antiseptic days, it is so no longer. It is far preferable, less likely to do harm, to perform open opera-

tive reduction, provided, of course, that one has a reliable aseptic technic. In dislocations which are more than a few days old, adhesions have formed and these should be broken by rotation in various directions, and by abduction and adduction before attempt is made at reduction.

In our medical schools emphasis is put upon the Kocher method, in many no other is taught. The Kocher method, a development of the Schinzingler, is clever and most dramatic. Moreover, it is made attractive by the excellent illustration which has been copied everywhere, particularly the patient's expression of relief when reduction has been effected. It utilizes the untorn posterior parts of the capsule as fulcrum somewhat as the iliofemoral ligament is used in reducing dislocations of the hip. The method will undoubtedly reduce a large majority of anterior dislocations, but unless used with caution, is dangerous. I have known of several unpublished cases of intracapsular fracture of the head of the humerus, one of my own. It is difficult to realize the enormous rotatory force which one can exert on the cancellous upper end of the humerus by means of the forearm used as a lever. I believe that any dislocation which can be reduced by the Kocher method can be reduced by the method of lateral traction and with less risk.

Not less dramatic is the method of Sir Astley Cooper: traction downwards and outwards, countertraction being made with the operator's fist in the axilla or if more force be required, traction made by the operator with both hands and his unshod heel in the axilla. The traction is followed by adduction. If adduction is made before the head is disengaged from beneath the edge of the glenoid, fracture is likely to result, a longitudinal fracture running from the base of the greater tuberosity downwards, emerging on the mesial surface of the shaft. At least I have seen one such case.

OLD UNREDUCED DISLOCATIONS

In time mobility slowly increases, a

new joint forms, ligaments adjust themselves so even a dislocated arm may be useful. The cases should be studied individually and treatment undertaken according to the nature and degree of disability. Many would best be left alone, others, because of pain, loss of function, should be operated upon. Some can be reduced after cutting the contracted soft parts, but with others one can do little but resect the head of the humerus.

HABITUAL DISLOCATIONS

In habitual dislocation it is often a question whether the trouble is due to faulty union of the rent in the lower part of the capsule, or to retraction and loss of support of the supraspinatus muscle. T. Turner Thomas has had good results from suturing the capsule through an axillary incision, Perthes by shortening or re-attaching the supraspinatus. Habitual dislocation may give no trouble as long as the arm is not elevated beyond the horizontal. This may be prevented by apparatus, a strap connected with a belt may suffice, as in swimming.

There are, of course, other causes of habitual dislocation than repeated traumatic dislocation with wide tears in the capsule, such as poliomyelitic paralysis, fracture of the glenoid diminishing its already small area.

COMPLICATIONS

Muscle rupture is so common as to be almost a necessary part of the process of dislocation, especially of the subscapularis, the supraspinatus is not rarely torn off its insertion, the biceps tendon may be dislodged from its groove and become an obstacle to reduction, but it is seldom divided.

Nerve injuries, sometimes with more than temporary paralysis, are not rare, also damage to the axillary vessels. I have seen gangrene of the hand from obliteration of the axillary artery in a forward dislocation of the shoulder.

Fracture of the greater tuberosity is

commonly due to impingement on the edge of the glenoid but its points of attachment of the dorsal scapular muscles are often pulled away. Stereoscopic x-ray films are here invaluable.

Fractures of the upper end of the humerus as complications of dislocation vary greatly in form, from transverse fracture of the surgical neck to comminuted splintering of the bone. Probably they are not all caused by the same mechanism. The most common is the transverse fracture of the surgical neck, which may occur by leverage, the abducting or extending force continuing after dislocation has occurred; the head held by untorn parts of the capsule, the edge of the glenoid, the fulcrum (Stimson's suggestion) or the surgical neck of the humerus in contact with the acromion. Dislocation complicated by fracture of the neck of the humerus, has rarely been reduced by manipulation, but it is difficult, often impossible. Then it is best to cut down on the fracture,

drill a hole into the remnant of the shaft which remains on the head, passing a wire or a hook, and make traction. The head is thereby readily replaced. The wire may be used to fasten the head and shaft together.

AFTER-TREATMENT

It is common practice to bind the arm to the side for two or three weeks to favor healing of the wound in the capsule, motion being gradually increased after this date.

While complete fixation is not of great importance, fixation will at least prevent abduction in which position redislocation easily occurs. Prolonged fixation is apt to result in the formation of symptom producing adhesions, so that there are some advantages in early mobilization. Such mobilization should take the form of elevation of the arm in the sagittal plane as less likely to disturb the union of the capsule.

SIMPLIFIED TECHNIC FOR INTRATRACHEAL INJECTION OF IODIZED OILS (LIPIODOL)*

A. L. SORESI, M.D.

NEW YORK

THE generalized use of iodized oils for the diagnosis and treatment of diseases of the respiratory organs demands a technic that does not require a specialist nor complicated apparatus, and that is safe and painless to the patient.

The reason why intratracheal injections are difficult is that the instruments required are rather imposing looking and cause fear, discomfort and sometimes actual pain. The patient becomes scared and restless, consequently with certain procedures the danger of allowing some of the oil to drip in the esophagus is actually present.

The technic described here has been

used several hundred times, the cases including nervous women and children, without the slightest mishap.

The technic can be considered absolutely safe and easy. *In fact the dripping of oil in the esophagus is a practical impossibility.* The patient is not scared because only an instrument resembling the plainest tongue depressor is used. Not even a head mirror or the projection of light in the throat is required.

The only instruments used are the special cannula tongue depressor and a record syringe of suitable size (10 to 20 c.c.). (Fig. 1.) The cannula tongue depressor is a metal tongue depressor adapting

* Submitted for publication November 9, 1929.

itself to the tongue closely and along which runs a metal tubing. This metal tubing projects from both ends of the

which is attached a suitable tubing. It is advisable never to touch either the tongue or the palate directly but allow the

FIG. 1. Two views of cannula tongue depressor with tip of syringe attached.

tongue depressor: The end that comes in contact with the posterior aspect of the tongue is bent to such an angle and projects enough to engage itself into the epiglottis. The other end is adapted for insertion of the record syringe, containing the iodized oil. (Fig. 2.)

The procedure recommended is the following:

FIG. 2. Cannula tongue depressor shown adapting itself to whole tongue while tip of metal tubing becomes engaged in epiglottis.

solution to drop on the tongue. This because some patients gag and cough

FIG. 3. X-ray of patient fully dressed while iodized oil is poured into trachea. Note how it is impossible for iodized oil to drip into esophagus.

The patient sits erect and is told to open his mouth and push the tongue forward.

The throat is anesthetized by dropping slowly (drop by drop) on the back of the tongue 20 per cent watery solution of novocaine, either with pledgets of gauze held by any forceps or by a syringe to

FIG. 4. Iodized oil in bronchi.

very easily and persistently when the posterior aspect of the tongue or the palate is touched. In a few minutes the posterior aspect of the tongue, the epiglottis and the larynx are anesthetized. In order to make sure that the anesthesia is satisfactory, ask the patient if he feels that his throat is numb, if so apply the cannula

tongue depressor and if no reaction follows you can safely start the injection.

(The syringe has been previously filled with lukewarm iodized oil and inserted into the cannula.)

As seen by the illustrations the cannula tongue depressor adapts itself closely to the tongue. The curved tip is engaged in the epiglottis. (Figs. 2 and 3.) All that is needed is to gently press the cannula tongue depressor on the tongue while gently pulling it forwards. Thus you are sure that in pulling the tongue forwards the tip of the cannula tongue depressor is and remains engaged in the epiglottis. Consequently with the organs properly anesthetized it is a *physical impossibility to cause dripping of oil into the esophagus even if the patient moves the head.* (Figs. 2 and 3.)

The injection will be more successfully and easily accomplished the less the patient has been frightened. You tell the nervous patient that you only want to apply the tongue depressor on the tongue. (You do not even need to look into the mouth); the actual injection then requires so little time that the patient will be most agreeably surprised to know that the whole procedure is over before he thought it had been started.

By the method described injection of iodized oil has become such an easy procedure that we do not even require our patient to undress or open their collars, when the latter are not too tight.

If it is desired to inject only one lung, all that is necessary is to have the patient lean slightly on the side which should be injected.

BURNS*

E. R. SCHMIDT, M.D.

MADISON, WIS.

BURNS are unexpected accidents and their sudden occurrence finds the victim and his comrades unprepared to meet the emergency. The first aid that is given is very important in the later treatment. The agents causing the tissue reaction or destruction are many: dry heat, moist heat, chemicals, mechanical friction, x-ray, actinic rays and electricity.

In each case there is a destruction of tissue, or a tissue reaction, and its influence on the human body will be directly proportional to the amount of toxin absorbed. The amount of toxin absorbed will depend on the area of the body involved. It is an old clinical observation that if one-third of the body area is involved, the prognosis is grave and often fatal. Children do not tolerate burns so well as adults; and with them, burns of the face, neck and head, as well as burns of

the large serous cavities, are more serious. The damages caused by burns, whatever the degree, are destruction of tissue, the formation of toxins, and the presence of secondary infection with the development of other toxins. These toxins are quickly absorbed, and the body has to take care of them. The circulation carries these toxins to the liver and kidneys, and they are eliminated through the kidneys. The kidneys show impairment by a reduction in the amount of urine and the presence of albumin, casts, and red blood cells in the urine.

The problem that presents itself in the treatment of burns then is the following: first, the prophylaxis; second, the emergency treatment; third, the treatment of toxemia; and fourth, the treatment for replacing the lost tissue.

The prophylactic treatment is lay educa-

* Submitted for publication December 10, 1929.

tion for the innocents and the educated: first, that fire will burn; and second, what will make fire. This has been carried on, but still there are people who will light a match to see if their gasoline tank is full.

The best emergency treatment is to summon medical aid, or take the patient to a hospital where proper aid can be given. The use of water on burns with different ingredients to relieve the pain and burning is a poor procedure, because this may wash off some of the toxins; also it will bring in more infection and, by moistening the destroyed tissue, aid in the absorption of the toxins. For the relief of pain, the clothing which causes pressure or dragging on the damaged area should be removed and then a 2.5 per cent solution of tannic acid should be applied by means of a spray every fifteen minutes until the destroyed tissue assumes a tan brown color and a coagulation takes place. Covering the burnt area will ease the pain, shut out infection and catch all the toxins in the coagulum and prevent their entrance into the body. During this procedure the body should be kept warm and symptoms of shock combated by means of warm drinks, such as coffee or tea, and the injured person kept flat on his back or side, depending upon where the burn is. In addition, morphine in sufficient doses should be used to relieve the pain.

Shock and toxemia have to be combated. Even if the coagulum takes care of most of the toxic products, there will be some absorbed, and shock in varying degrees will be present. The recumbent position, or lowering the head of the patient, the maintenance of the external body heat, and the administration of fluids will combat shock and aid the body in eliminating the toxins. What fluids are the best? It is our practice to give our first fluids intravenously in order to give the patient immediate benefit. This is done where there is a moderate degree of shock. Six hundred cubic centimeters of a 5 per cent glucose solution are given. This seems to increase the blood volume,

dilutes the toxins, and brings 120 calories of available energy to the body. Normal saline solution is given as proctoclysis. The degree of shock and its persistence or improvement is determined by means of blood pressure readings every fifteen minutes, watching the pulse rate, and the general condition of the patient until there is an improvement warranting a greater interval. The effect of toxins on the body is watched through the urine. The total twenty-four hour output, and its complete examination, compared with the twenty-four hour intake will give fairly accurate evidence as to the degree of absorption and the influence on the kidneys. By the use of this method, where there ordinarily is scanty, high specific gravity urine with the presence of albumin, casts, and red blood cells, we find an almost normal urine. This method combats the absorption of toxins through their being caught in the coagulum. Infection which may enter is at a minimum, since absorption is prevented when the toxins are shut off from the capillary system. Shock and what little absorption might take place are treated with glucose and saline solutions. The vicious circle present in the older forms of treatment is broken by almost completely eliminating the toxic products that follow thermal destruction of body tissue. The reason for not using any oily solutions in the emergency treatment is self evident. If an oily solution is used first, the aqueous solution of tannic acid will not be able to permeate the destroyed tissue so completely, and more absorption will take place.

The repair of tissue defects and restoration of function are very important. The restoration of function should always be in mind from the very beginning. Limbs should be placed in the proper positions, but that alone is not sufficient. As healing takes place, the limbs that were in proper positions are soon drawn into improper positions. Hence constant care must be exercised. The closure of defects may be greatly aided by timely grafts of skin,

either Thiersch, Reverdin, or whole thickness of skin. The sooner this is done, the better the result will be. As soon as the coagulum is ready to fall off, there is a bed of granulation tissue. This will immediately become more heavily infected if not protected. Our practice has been to use hot boric and alcohol dressings, changing them every four hours until the granulation has developed a healthy red color. The night before the graft is to take place, the whole area is painted with one-half strength iodine solution and a dry dressing put on. This dressing is removed the next day,

and Thiersch grafts are laid on. These grafts are covered with a wire cage, and sterile gauze is placed over the cage. It is not changed for twelve days. Then the crusts of serum are removed and the field is almost entirely covered with new skin. After this just a dry dressing is used; or, if this sticks, a boric ointment dressing is used instead. To obtain a complete return of function where it is impaired will necessitate careful medical care. Massage, exercises, and plastic operations should all be used at appropriate times and when indicated.

PESSARIES IN GYNECOLOGY*

GEORGE W. PHELAN, M.D., C.M., F.A.C.S.

BROOKLYN, N. Y.

THE art and practice of medicine is in continual flux—new ideas and methods supplant the old, as it should be, but occasionally a good method is lost sight of in the seeking of the new, and this we find to be true in the use of the pessary. It has been described as a “lost art,” and one has only to scan the various medical indices to be appraised of this fact, for today there is hardly an article written on the use of the pessary, while twenty years ago, thousands of printed pages sought one’s attention.

The decline in the use of the pessary can be traced in large measure to the wide field that a more perfect operative technic has opened, to a consequent limiting of the indications for the use of the pessary, to a more proper interpretation of pelvic pathology and to a crowded curriculum in the medical school, this teaching often being of a more scientific nature, replacing in turn methods that perhaps are at times empirical and unscientific, and yet of inestimable value to the specialist and general practitioner.

In the days gone by many a heated

argument was heard as to whether a pessary is a lever, a crutch or what-not. In order that we may not transgress to useless polemics, let us state that it may be at times any of the things that its old protagonists proclaimed, but above all, it is a support, and if we consider it as such, the indications of its use and the contraindications thereof can be the more easily evaluated.

The pessary has also been the cause of verbal wars, not only as to the material it should be made of (wool, hair, thread, silver, gold, platinum, horn, bone, wood, celluloid, hollow tin, German silver, glass and rubber in all its varieties, and still the list is not exhausted), but also the shape it should assume, so that in a catalogue of years gone by there were pessaries of every shape and size made of many different materials and all bearing a separate and infallible promise, the name of the man who devised that particular shape or added that particular curve, so that the poor doctor, with his many and varied duties, instead of becoming a pessalogist, became a pessimist, and

* Submitted for publication December 14, 1929.

perhaps another reason added why the pessary has lost caste. At the start let us say that we shall not give you a long

dissipated; that the intellectual and spiritual being may be elevated from the lowest states of depression, bordering on melancholy,

FIG. 1. A. Hodge pessary. B. Albert Smith pessary. C. Thomas pessary. (From Crossen's "Diseases of Women," C. V. Mosby & Co.)

galaxy of names, famed for their pessaries, but rather to point out that each and every pessary must bear the imprint of the doctor using the same.

What then can we say in defense of a practice that has in many ways been relegated to the ground of "has been?" Only this, that a pessary when properly applied in the proper case is a most valuable aid, not only to the patient but to the doctor, relieving pain and discomfort, and at times enhancing a more normal physiology, resulting in turn in a cure of the condition complained of; and, furthermore, it is a most servicable aid for those cases on whom an operation is not advisable, whether it be for age or constitutional illness, etc.

It might prove of interest if we quoted the opinion of one of the masters in the not too antiquated past. I quote from "Diseases Peculiar To Women" by Dr. H. L. Hodge, 1860:

The long experience of the author in the use of pessaries will perhaps justify the expression of his opinion . . . that the local symptoms of weight, pain, etc., the leucorrhœa, the menorrhagia and the dysmenorrhœa, and all the innumerable direct and indirect symptoms of spinal and cerebral irritation, including neuralgia, nervous headache, nervous affections of the larynx, lungs, heart, stomach, bowels, etc., as also spasms, cramps and convulsions, may often thus be

or be delivered from the highest degree of maniacal excitement; and that the whole economy may thus be revolutionized.

Quoting further on the reflex influence of the pessary at the time of introduction: "'Oh, Doctor!' exclaimed a cheerful and intelligent lady, 'you hurt my neck, my shoulder, my side, my knee,' and all this in rapid succession, each spot being relieved before the other was involved. Another exclaimed on the removing of an instrument, 'Doctor, you hurt me.' 'Where?' 'At the top of my head.'"

Today that sounds not unlike an advertisement for some patent cure-all, but when we consider that operations in 1860 of even a minor character were fraught with grave risk, it is not hard to find a reason for their enthusiasm, and should indeed make our indications most modest indeed.

The word "pessary" is an old one, being derived from the Greek *πέσος* and designating a curved stone that was used in playing a game something like our shuttleboard. Later it was used to designate a plug of wood or lint, steeped in medicinal substances to be introduced into the vagina or anus, etc. This definition still holds good for our medicated pessaries, and, at a still later date, to designate a support for the weakened pelvic structures.

In what type of case is the pessary

indicated? Broadly speaking, any type of case in which the pelvic support is inadequate, allowing in turn the uterus to depart from its own anatomical integrity or the bladder to herniate.

These cases can be further classified as:

1. Constitutional.
2. Acquired.

And in passing will say that it is from the latter that the larger number of cases are obtained.

Remembering the afore-mentioned broad classification, remembering that the pessary is but a support for the most part, but seldom producing a cure, we must limit our indications to those cases on whom a permanent cure (operative?) is not advisable:

1. Constitutional causes, such as old age, debility, tuberculosis, etc.
2. Marital, because an operation may interfere with the patient's fertility (post-operative inflammation), but more important pregnancy will most often undo what an operation has done, therefore necessitating another operation. And while we are remembering, *note*: that operations, of this type carry a definite, small to be sure, mortality, not speaking of morbidity with its often invaliding results.
3. Those who refuse operations.
4. Therapeutic.

Before passing to a consideration of the cause and the type of these anatomical deviations, it is well for us to keep some simple picture of the anatomy concerned, and I have borrowed from Crossen's "Operative Gynecology," as epitomizing this subject most clearly and briefly:

The pelvis is spanned by two planes of supporting tissue, one above the other. Each plane is attached to the pelvic wall practically all the way around, so that it forms a fibro-muscular diaphragm with sling action transversely and diagonally as well as antero-posteriorly.

The lower plane or diaphragm lies principally below the vagina and consists of the levator and muscle of each side, with its fascial sheath formed by the recto-vesical

fascia above and the anal fascia below, and supplemental muscular and fascial structures in front and behind. Of the three openings through this fibro-muscular support, the rectal opening is well protected by the sharp bend in the canal and by the superimposed sphincter muscles below, while the urethral opening is protected by the narrowness of the canal and its situation immediately under the resisting bony arch. The vaginal opening is the weak area in the pelvic floor. Under normal conditions it is fairly well protected (a) by its situation, well forward, out of the line of direct pressure; (b) by the direction of the canal being such that intra-abdominal pressure tends to close it instead of open it; and (c) by the overlying upper fibro-muscular plane and body of the uterus.

The upper plane or diaphragm lies above the vagina and comprises two segments—the uterine segment and the vesical segment. Each segment consists of a viscus and its surrounding supports. The uterine supports in the upper plane are (a) the broad ligaments, laterally, (b) the utero-sacral ligaments, posteriorly, (c) the utero-pubic fascial plane, anteriorly, and (d) the fibres between these, extending diagonally from the uterus to the pelvic wall and completing the fibro-muscular diaphragm. Each broad ligament contains an upper and a lower band or condensation of supporting tissue (connective tissue and scattered muscle fibres). The lower collection, extending from the cervix outward and upward to the pelvic wall near the "white line," is much the stronger of the two. In fact, it is so important that it has been called the "ligamentum cardinale" of the uterus. The bladder supports in the upper plane are the utero-pubic fascial plane and the banks of this tissue extending from the bladder to the uterus and to the broad ligaments along the ureters and to the pelvic wall and to the pubic bones. Both the uterine and vesical segments receive support, also, from the intact lower plane.

In addition to these two strong supporting planes, which directly resist intra-abdominal pressure, there is another factor which has much to do in maintaining the integrity of pelvic support. The factor is the deflecting mechanism, by which the force of intra-abdominal pressure

is deflected from the weak area and distributed over the supporting planes. This mechanism depends upon the normal

the same, and thus still further providing against protrusion at the vaginal orifice.

When the pelvic floor has been torn

FIG. 2.—Introducing pessary. Index finger is passed to top of posterior end, which is then depressed until it can be pushed past cervix, as shown in Figure 3. (From Crossen's "Diseases of Women," C. V. Mosby & Co.)

anterior position of the corpus uteri. When the uterus is displaced backward, the deflecting mechanism is disarranged. This is one reason for the importance that attaches to backward displacement of the uterus. Aside from the symptoms caused by retrodisplacement and its complications, there is this disarrangement of the deflecting mechanism, which, in the child-bearing woman, usually leads to serious loss of support sooner or later. With the uterus in normal position, the intra-abdominal pressure is received on the posterior surface of the organ and distributed over a wide area of the supporting planes. Even though the vaginal opening has been enlarged and weakened considerably, it is protected from the abdominal pressure by the broad, firm deflecting surface just above. The greater the pressure from above, the more firmly is the protecting corpus uteri pressed over the opening. Again, as the corpus uteri is pressed downward and forward the cervix is pushed backward, putting the vaginal walls on the stretch and approximating

FIG. 3.—Introducing pessary. Posterior end depressed and being pushed past cervix. (From Crossen.)

and the uterosacral ligaments stretched so that the cervix comes low and the corpus uteri goes back, the whole mechanism, by which the intra-abdominal pressure is resisted by the two planes, is disarranged and the uterus and bladder and anterior rectal wall are gradually forced down.

In reviewing the causes of these anatomical deviations, we find but few, but these few are very definite: (1) Constitutional: Almost any condition that causes weakness and asthenia. (2) Increased intra-abdominal pressure: Occupation, play, cough, corsets, binding after delivery, sub-involution, tumor and cysts, trauma, etc.

1. Constitutional. Consult an internist to determine whether the so-called constitutional weakness is a necessity or not.
2. Increased intra-abdominal pressure.
 - (a) Occupational. Needless to say, in advising a patient to change her occupation, it is with the knowledge that even an operation offers no guarantee of a permanent cure.
 - (b) Play. Discontinue.
 - (c) Cough. It would be indeed folly

to treat a pelvic condition, perhaps a minor one, without determining the cause of a persistent cough, for here often many of the symptoms complained of, despite a departure from a normal anatomical integrity, will be remedied by curing the cough, thus stopping the unceasing change in pressure to which a chronic cough subjects the pelvis.

- (d) Constipation. One could write at length, even though at variance with some of our leading gastroenterologists, but bear in mind that the pelvic organs are in intimate association with the sigmoid and upper rectum, and despite the fact that no constitutional ill-effects may be detected at times from the constipation, yet the pelvic distress may be due in part or in whole to this very thing. Also, constipation usually means straining at stool, and thus a marked increase in intra-abdominal pressure is brought about.
- (e) Corsets. The passing styles indeed can play a part, as it is rumored that with the event of the long skirt, corsets with bones (and they allow less play than the others and caused increased intra-abdominal pressure) are essential to produce the true "feminine lines." A short time ago the "boyish figure" was the approved style.
- (f) Binding or tight girdles after parturition. But rarely and then only where the integrity of the abdominal wall has been destroyed is there any indication for such treatment. Postpartum exercise early and late is the best method to insure a good abdominal wall, and in turn aid in the proper involution of the uterus.
- (g) Subinvolution. The cause: usually lack in postpartum attention, such as exercise, posture and

a proper appreciation of the size the uterus should be, and, the speed at which involution should proceed.

- (h) Tumors and cysts. Little can be done to avoid these complications.
- (i) Trauma save obstetrical. Rarely due to other than operative trauma. In many of the minor gynecological operations it is the method to grasp the upper and lower lips of the cervix with tenaculæ, and that is where their function should cease, simply to fix the cervix; but it is the habit with many operators to drag on the cervix, thus pulling it, and, of course, the fundus as near the valva opening as possible. This dragging may definitely and permanently impair the pelvic support.
- (j) Obstetrical trauma. Despite the fact that some authorities say parturition is a pathological process, we still feel that "intelligent watchful waiting" is another aid in our prophylaxis against the solution of normal pelvic continuity.

Thus in a brief review of the more common causes of these departures from the normal we see that much in a prophylactic way can be done by proper advice, instruction and technic.

With what anatomical deviations are we concerned? Briefly, those in which the axis of the uterus has been changed and where the level of the uterus, i.e., the body and cervix, departs from normal; deviations of the uterine axis as a whole and not as a part, i.e., versions of the uterus and not flexions; the level of the uterus as judged by the tip of the cervix resting on a line joining the spines of the ischium or on an arc drawn therefrom. Naturally, there are exceptions to these rules, but on the whole they will serve as a guide.

We have previously stated "which allows the uterus to depart from its own anatomical integrity." This statement has been made advisedly as it is in the depar-

ture of the uterus from its congenital position to a new position that produces, as a rule, pelvic pathology and symptomatic distress.

By various authorities the position of the uterus is stated to be retroverted in 16 per cent to 18 per cent of all virgins and for these patients that position is considered as one of normal anatomical integrity. Furthermore, in these cases of congenital retroversion, discovered at examination and not an etiological factor in the patient's history, no attempt should be made to correct that which is normal for that patient.

We see then that our pessary is even further limited by this fairly large type of cases, and so it is, for the most part, in the acquired retroversion from whatever cause save tumors, in antiversion with early descensus and in all types of descensus and herniation of the bladder that the best results are obtained in the use of the pessary. The pessary in these cases acts as a support and by allowing a return of normal circulation, relieving the strain on muscle, fascia and connective tissue, tone is enhanced, involution or repair aided, and a cure at times effected.

Let us digress a moment to view in our mind's eye this action. If we draw a plane of the upper pelvis on a level of the anterior vaginal wall, it has somewhat the appearance of a pear cut in its long axis. If we view it on the side, it has the appearance of the letter "s" placed in a lateral position with its curves lengthened. If the pelvis is again viewed in coronal section, we see it has somewhat the shape of a "v." This is due to the levators, and it is the levators that support the pessary, and it is on the integrity of the levators that we depend for the final support transmitted through the pessary. On the other hand, in using a pessary of the horse-shoe shape the action of the levators is not only one of clasping and supporting, but also of buttressing.

For the most part, we favor the shape of the Hodge or Gehrung after one has

modified it to the pelvis in consideration. Both can be bought in various sizes, but, because each vagina varies in length, breadth, and symmetry (depending on the integrity of the levators), we favor the shaping of each pessary at the time of introduction, hence, each pessary should bear the imprint of the doctor using the same.

That the symmetry of the pelvis is important can be easily ascertained by examining a patient after a labor. We may find one side fairly normal, the other presenting definite indications of the disruption of the levators. Naturally, if a pessary is introduced without proper evaluating, this observation, it may prove a complete failure, so it is by considering each vagina to be fitted as an entity, distinct, separate and different, in that way alone will the pessary prove a success. It is true that a stock pessary may prove efficacious, but the converse is equally true.

In order that the best results may be obtained, we advocate the use of the hard rubber pessary, and keep in stock various sizes of the simple round variety. This is advised as hard rubber is the only material that is easily shaped, cheap, smooth, and, if properly cleansed, seldom shows the action of corrosion.

After an examination, at which time the use of the pessary is decided on, two or three pessaries of varying sizes are placed in boiling water (sterilizer) and allowed to soften, and then while soft bent to the required size, immediately placed in cold water, when they will harden at once. The length is best judged in the same manner that we seek to find the diagonal conjugate i.e., by introducing the first and second finger to the posterior fornix and measuring from the subpubic ligament. The width only by trial and experience.

It must be remembered that often several trials are necessary with alterations in shape and size before the ideal is attained, and the ideal pessary must fit and perform

the function assigned to be a success. Furthermore, the ideal pessary will not cause pain or distress, in fact, the patient should not be conscious of its presence and it should not interfere with normal marital relations.

The diagrams show us roughly the shape of the two pessaries in question. The first is best introduced in the oblique diameter of the outlet. After lubricating the pessary, the perineum is depressed with one or two fingers of the left hand, the pessary held in the right at the narrow anterior bar, and then inserted in the oblique diameter, so that the anterior arm will pass to the left of the urethra while the posterior arm will press down and fit in the groove formed by the union of the perineum and the right vaginal wall. Pressure down is made, and the pessary is forced gently forward until the resistance of the pelvic floor is overcome when it is gently rotated, bringing the anterior bar down and the posterior bar up. The cervix should pass over the posterior bar, in other words, lie in front of the posterior bar. Sometimes it will be found that the cervix is posterior, and then it is necessary to depress the posterior bar with one or two fingers in the vagina until the posterior bar slips behind the cervix. Your pessary is now clasped or supported by the levators, the lateral vagina walls are rendered more tense, and at the same time the utero-sacral ligaments are rendered taught and tend to pull the cervix posterior, displacing the fundus anterior. One can easily understand that with the uterus in position herniation of the bladder will also be aided, as the facial sheath that supports the bladder will be rendered more taught and the two arms of the pessary will act as a support or scaffolding.

The Gehrung pessary is easily fashioned from the round type previously mentioned. This is done by approximating two opposite points on a softened pessary. If now it is bent in the middle of its long arms, we obtain the shape of two horseshoes placed a few centimeters

apart and joined at the corresponding point or its fellow. This pessary can be bought in various sizes, but with different cases so must this pessary vary, in height, in width of the two arches and the symmetry of the same. This pessary is used to its greatest advantage in herniation of the bladder, to a much less degree in early descensus. Its action is one of support of the bladder, and acts directly at the site of the torn or stretched bladder support. This pessary depends not only on the grasping action of the levators, but also is buttressed against some bundle of muscle fibers. This pessary is introduced by depressing the perineum and at the same time inserting the left heel as far as it will go easily. It is then carried posterior, and during the whole time of its introduction is rotated in a corkscrew manner so that when the heel is at rest, it will lie opposite its fellow, but on the right side, thus bringing the two arches of the pessary directly under the bladder.

In the use of the pessary, we are striving to correct anatomical deviations. There is little to be said in a controversial manner in regard to the first three indications, i.e., constitutional, marital, those who will not be operated on, but what of the fourth, therapeutic? In evaluating slight digressions of the uterus from the normal, one is at once struck by the seemingly contradictory findings. In the one case a patient with definite retroversion and prolapsus may offer no complaint, while on the other hand, one with what seems but slight laxity of the uterine support, the tip of the cervix being just below the line joining the ischial spine, may present a number of symptoms varying from pelvic complaints to definite neurological symptoms, and it is in such cases that lifting and supporting the uterus with a pessary will prove whether that is the exciting cause of the symptoms.

In order that I may illustrate this important feature, I will briefly review 2 cases. The first one complained of persistent diarrhea that had existed since the

birth of her last baby some twelve months before. It was the one symptom complained of. She was seen in the clinic after passing through various other departments without relief. The finding was just one, a uterus anterior with a departure from its normal level. Rectal examination revealed the fact that the cervix was invaginating the anterior rectal wall. A pessary was tried. The diarrhea was stopped.

Another woman presented herself at the clinic, after having been reviewed by the other departments and labeled with a diagnosis of neurasthenia. Her complaint was pain at the base of the skull and upper cervical spine. The findings here were a simple departure of level. A pessary was tried, and the patient returned without the pain. She is still under observation as she is in the child-bearing age and desires more children. The recital of these 2 cases may sound extreme, but it is only by trying, in cases where there is but slight and early departure from the normal, that we are able to evaluate a simple, single clinical finding.

The "do not's" are important in the use of the pessary. Do not insert a pessary with the uterus retroverted and expect the pessary to right the condition. First correct the retroversion manually, and if it is not correctable, it is not a case for a pessary.

Do not use a pessary in the presence of pelvic inflammation.

Do not use a pessary in the presence of vaginal inflammation.

Do not use a pessary to correct a malposition caused by tumors or cysts.

Do not allow a pessary to remain that causes pain.

Do not forget with the presence of prolapsed tubes and ovaries the pessary is not to be inserted.

Do not forget that proper exercise: knee, chest, monkey-trot, etc., is indeed an added aid.

Do not forget that when the pessary is in place the tip of the finger should be able to pass easily between the supporting arms and the vaginal walls.

Do not forget that a warm cleansing douche should be taken every day except when the patient is menstruating.

Do not forget to see your patient two weeks after the first introduction of a pessary.

Do not forget that a pessary should be removed and cleansed at least every six weeks. Do not forget that at the time of its removal, if signs of pressure are present, that it must be discontinued until such signs are absent (such signs are for the main visual); and, in conclusion, do not forget the words of the late Dr. Emmett: "The great cause of failure and disappointment in the use of pessaries lies in the fact that the vagina is expected by many to adapt itself to any instrument which may be introduced, when, in fact, it is essential that the peculiarities of each individual case should be studied."

WET & DRY DRESSINGS WHEN & HOW TO USE THEM*

CARL L. HOAG, M.D.

SAN FRANCISCO, CALIF.

IN general we are called upon to treat two kinds of wounds: clean wounds (clean in the sense that there have been relatively few organisms penetrating the skin) and those that are frankly suppurative. Cuts and lacerations, if seen

in the first twelve hours, should be regarded as clean wounds for the purpose of selecting a dressing, as a very large majority should heal without suppuration. These wounds are not bacteria free but the number of bacteria is so small that normal tissue

* From the Department of Surgery, Univ. of California Medical School. Submitted for publication Dec 7, 1929.

reaction is able to destroy the few present without the formation of pus. In applying a dressing, the surgeon can act only to prevent the invasion of more organisms from without, and to so support the tissue that bactericidal action can take place to the maximum degree. Rest to the part and heat for dilatation of blood vessels are our best agencies for the latter.

There are four major requirements for the multiplication of bacteria; namely, the organism, a media, moisture and heat. Lacking any one of these, the process does not occur. Body heat and tissue media are always present in wounds. If we attempt to reduce the number of bacteria by drugs or by washing out the wound we are seldom successful in materially eliminating them. We can, however, render the wound relatively dry. It is the most satisfactory point of attack. Dressings which prevent the invasion of more bacteria and will absorb the greatest amount of moisture and continue to do so for the longest period should be selected. We therefore use ordinary gauze. Its capillarity removes moisture and passes it to the outside where it evaporates. Any covering over gauze preventing evaporation and continuous dehydration of the wound destroys its greatest value as a dressing. Too frequently we cover a gauze dressing with so much adhesive, oil-silk, wax paper, cotton or fiber pads that absorption is insufficient to keep the wound dry and a typical incubator is produced, bacteria multiply, and maceration occurs. If additional heat is desirable to increase the vascularity in these dry wounds, it can better be applied by the use of the hot-water bag, electric light or electric pad than by impervious coverings.

I think we should consider our drugs in much the same light. Those that destroy bacteria without devitalizing normal tissue cells and at the same time inhibit their growth by dehydration or isolation are of the greatest value. In the possession of these properties, for instance, lies the value of tincture of iodine.

Just as we should attempt to keep wounds free from suppuration by properly applied dry dressings, if pus does form it must be removed from the scene of action immediately. Our gauze dressing will absorb pus as it does moisture, but to a much less degree. Either the dressing must be changed frequently or we have again the typical incubator at body temperature. It is impracticable to change dressings often enough to keep wounds dry so we substitute wet dressings in an attempt to dilute the pus and make it more absorbable. This type of dressing is only a makeshift for a more complete removal of the products of bacterial action, by irrigation or soaking, because it can be used as an ambulatory measure. Usually the dilution is sufficient to allow the regenerating tissue cells to throw off the invading bacteria. Many solutions are advocated and are of value as they promote an interchange of fluid with the pus discharge, and actually accomplish dilution. Perhaps some solutions are bactericidal, but I believe this action is secondary to the principals of drainage. The use of an impervious covering for wet dressings, while it protects the clothes and keeps the dressing moist for a longer period, too frequently produces a "poultice" action in practice in which the temperature of the part is raised, secretions retained, and suppuration speeded up.

It is better to give the patient a bottle of solution to keep his dressings constantly wet than to retain moisture by impervious coverings.

Where the skin is not broken, as in contusions, sprains, etc., relief is usually secured by any type of heat. The extravasated blood and broken-down tissue are carried away through the blood and lymphatic streams. Heat promotes this absorption. Hot wet dressings give an excellent distribution of heat and there can be no objection to impervious coverings. Here, however, it is heat which is of value rather than the wet dressing.

Low-grade infections, paronychia, lym-

phangitis, infected hair follicles without suppuration, etc. may be treated in the same manner. Again, heat can be well applied through the agency of the wet dressing just as it can through hot solutions, the hot-water bottle or the electric pad.

In suppurative processes such as boils, abscesses, suppurative tenosynovitis, etc., where the skin is still unbroken and the infection not localized, a hot, covered wet dressing not only acts as a "poultice" to localize the infection but also softens the skin and helps the process to point. After drainage has been secured either by natural or surgical method, as already

suggested, the wet dressing should be left uncovered.

In selecting a wet or dry dressing for any lesion one must decide just what is to be accomplished, whether it is protection from more infection, dehydration, removal of bacteria present, a "poultice" action or simply support of the body resistance by the use of heat. For the most part, if dressings are to be dry they should be kept very dry. If wet, they should be very wet and be kept wet. If compresses or "poultices" for walling off infections through the agency of heat are required, use them but do not make an incubator out of an infected wound by sealing the dressing.

OFFICE LABORATORY FOR THE SURGICAL PRACTITIONER*

MAX LEDERER, M.D.

BROOKLYN, N. Y.

WITH the development of laboratory practice, its importance and necessity in diagnosis and treatment, and the opportunities for postgraduate instruction in the large cities, an increasing demand has arisen on the part of the practitioner far removed from elaborately equipped laboratories for such service. Within certain limitations, as to equipment and training, much of this work can be done in the office. The expense of such equipment and maintenance need not be large. The technical training necessary for the performance of the tests can be easily acquired, and the experience needed to read the results is soon obtained. The practitioner will probably face his most difficult problem in the interpretation of results. The solution here, however, lies in reading and the general knowledge of medicine, and can be learned by him who is willing.

To attempt to differentiate between a

laboratory designed for surgery and one for general medicine, is practically impossible. Since the practice of surgery depends almost entirely on general diagnosis, especially when cases are not referred for surgical treatment after careful study, what is applicable to that specialty, also applies to medicine as a whole.

Therefore, for practical purposes, the description that follows is a general outline of the equipment and procedures applicable to the country practitioner's office, with a few omissions in deference to surgical practice.

The detailed equipment of small articles need not be itemized. They can be enumerated from the descriptions of the tests, where the names and specifications will be mentioned. Any solutions, reagents and equipment here listed may be purchased in surgical supply stores or laboratory specialty houses.

The procedures to be described have

* Submitted for publication November 19, 1929.

been carefully selected from the manual of laboratory procedure of the Pathological Department of the Jewish Hospital of Brooklyn, and are described as they are done in that institution, with the equipment as used there. For reference purposes, any one of the following volumes should be at hand: Todd and Sanford's "Clinical Diagnosis by Laboratory Methods;" Webster's "Diagnostic Methods;" Vogel and Famulener's "Laboratory Methods," or Haden's "Clinical Laboratory Methods." The interpretations and significance of the tests will not be discussed.

Extensive bacteriological examinations cannot be attempted for obvious reasons. Examination of smears, especially for gonococci and the more common organisms, can be done with a minimum of equipment and time. For this purpose the Gram stain is used. With a platinum loop a small amount of the material is thinly spread on a glass slide. The preparation is fixed by passing the slide over the Bunsen flame three times. The slide is then grasped with a slide holder and carbol gentian violet is poured over the smear. After allowing it to remain for a minute, it is poured off and replaced with Lugol solution. This is again poured off and alcohol 95 per cent is dropped on it until the violet color has disappeared. The slide is washed in tap water and stained for a minute or two with solution of basic-fuchsin. It is then blotted, dried, and examined with the oil immersion lens. The Gram-positive organisms appear black or deep purple in color. Streptococci and staphylococci are easily identified by their characteristic groupings. Gonococci are red, occur in pairs, are coffee-bean shaped and frequently are found within the leucocytes.

The examination of urine often yields information of considerable value to the surgeon. The examinations which follow are within the scope of usual office practice:

URINE

Albumin. Test for albumin by filling a $5 \times \frac{5}{8}$ in. test tube three-quarters full

with urine. The upper portion of the specimen is boiled over the Bunsen flame, 3 drops of 2 per cent acetic acid are added and the boiling is repeated. The density of a precipitate is noted and recorded as follows:

No Turbidity: negative.

Slight turbidity: very faint trace.

Next degree of turbidity: faint trace.

Then: trace.

Then: moderate trace, heavy, cloud, or solid.

Sugar. The quantitative estimation of sugar is conveniently done by pouring 5 c.c. of quantitative Benedict's solution into a $6 \times \frac{3}{4}$ in. lipped test tube. The solution is boiled over a Bunsen flame, and while boiling, urine is added drop by drop from a Mohr 1 c.c. pipette graduated in 0.01 until a white precipitate appears. The amount of urine used contains 0.01 gm. glucose. The percentage of sugar is obtained by dividing 1 by the volume of urine used. Thus, if 0.5 c.c. of urine was used, $\frac{1}{0.5} = 2$ per cent.

Indican. Equal parts of Obermeier's reagent and urine are mixed in a $5 \times \frac{5}{8}$ in. test tube. To this is added 1 c.c. of chloroform. It is gently but thoroughly mixed and allowed to stand for a few minutes. A blue color of the chloroform which settles to the bottom indicates the presence of indican.

Acetone. With the aid of heat, dissolve 1 or 2 crystals of sodium nitroprussiate in a few drops of water in a $5 \times \frac{5}{8}$ in. test tube. Add 5 c.c. of urine and a few drops of glacial acetic acid and shake thoroughly. Over it layer carefully 1 c.c. of ammonia. A purple ring at the line of contact denotes the presence of acetone.

Blood. In a $5 \times \frac{5}{8}$ in. test tube dissolve a few crystals of guaiac resin in 1 c.c. of 95 per cent alcohol. To this add 10 c.c. of urine and 1 c.c. of hydrogen peroxide and shake. A green color indicates a positive reaction.

GASTRIC CONTENTS

Acidity. Examination of gastric contents should always be performed as soon

as possible after specimen is received. The appearance of the specimen should be noted and fresh particles of blood should be looked for. The specimen is then filtered through gauze. To 10 c.c. of filtrate add 1 drop of Toepfer's reagent. A red color denotes free hydrochloric acid. From a 50 c.c. burette graduated in tenths, add decinormal sodium hydrate solution drop by drop until the color becomes a canary yellow. The amount of the solution added, multiplied by 10, represents the percentage of hydrochloric acid in terms of normal hydrate solution. To the same filtrate now add 2 drops of 1 per cent phenolphthalein solution. Continue to add sodium hydroxide solution until the solution changes from yellow to red. This reading times 10 plus the percentage obtained for free hydrochloric acid, represents the total acidity in terms of normal sodium hydrate solution.

Lactic Acid. To determine the presence of lactic acid take 10 c.c. of water in a $5 \times \frac{5}{8}$ in. test tube. One drop of 10 per cent ferric chloride solution is added. Shake thoroughly. To this add 2 or 3 drops of filtrate. The presence of lactic acid is then indicated by a bright canary yellow color.

BILE IN FECES

Bile is detected by mixing feces with saturated solution of bichloride of mercury and allowed to stand over night. A pink color denotes bile. The feces should be examined for red blood cells, white blood cells, ova, and parasites, microscopically.

Examination of feces for blood is done as for the urine.

BLOOD

It is scarcely necessary to describe in detail the methods for counting blood cells. In surgical practice however, there are certain examinations that should be done and in the opinion of the writer are of great importance.

Bleeding Time. The lobe of the ear is pricked and the time is noted; the piercing

being done with a sharp needle. The blood is removed as soon as it accumulates, by lightly touching the tip with ordinary blotting paper. The time that the bleeding stops of its own accord is noted. The period of time between the beginning and the cessation of bleeding is known as the bleeding time. The normal bleeding time is one to two minutes.

Coagulation Time. This is best determined by the use of a capillary pipette which can easily be made from ordinary glass tubing about 4 mm. in diameter, the tubing being heated in the Bunsen burner and drawn out while hot. The blood is collected in such a capillary pipette about 6 cm. long from a finger tip puncture, and the time is noted. This pipette is then gently broken at one minute intervals and time of first appearance of the clot is noted. The difference in time between the finger puncture and the first appearance of clot is noted as coagulation time. Normally, by this method, it is up to nine minutes.

Blood Sugar Estimations. Blood sugar estimations can be conveniently done by the micromethod, as described by Kramer and Gittleman. The blood is drawn from the finger tip into a special pipette (marked 0.1 c.c. to 0.2 c.c.) up to the 0.1 c.c. mark and expelled into a $4 \times \frac{1}{2}$ cm. test tube graduated at the 2 c.c. mark and containing 1.5 c.c. of distilled water. The pipette is washed by drawing and expelling the solution several times. One-tenth cubic centimeter each of sodium tungstate solution (10 per cent aqueous) and two-thirds normal sulphuric acid are added. The contents are mixed by rolling the tube between the hands until the mixture changes to dark brown. The volume is then brought to 2 c.c. with water and mixed. It is allowed to stand for five minutes and centrifuged for two to three minutes. To 1.5 c.c. of supernatant fluid add 2 c.c. of copper solution in a sugar tube. Prepare the standard in a similar manner. Put both tubes in boiling water bath for six minutes and then cool. To each tube add 2 c.c. of phosphomolybdic

solution followed by water up to 12.5 c.c. Set standard at 15 and read in colorimeter.

Calculation is $\frac{S}{R} \times 0.1 \times \frac{1000}{7}$ mgm. per c.c.

S = reading of standard. R = reading of unknown.

The reagents, including the standard dextrose solution mentioned, may be purchased prepared for use and are stable. The assembled apparatus for this method is supplied by laboratory supply houses.

Icterus Index. The icterus index is done on the blood serum. About 10 c.c. of blood are collected in a test tube, allowed to clot and the serum is carefully pipetted off. The depth of the color of the serum is compared to a standard consisting of potassium dichromate solution, 1:10,000 in water, in any standard colorimeter. Should the serum be of a much deeper color than the standard, suitable dilution with water must be made. The result is obtained by dividing the reading of the serum by the reading of the standard and multiplied by the dilution, if any is made. The normal varies between 5 and 6.

Rosenthal Test for Liver Function. Blood is drawn off and serum is collected. Through the same needle the necessary quantity of bromsulphalein is injected, according to directions on the box. Fifteen minutes later, and one hour later, specimens of blood are again withdrawn from the vein. The serum is allowed to separate and is pipetted off. To each of the three specimens of serum, 1 drop of 5 per cent sodium hydrate solution is added. A purplish discoloration denotes the presence of dye. Normally, the first tube should contain no dye, the second tube very little if any, and the third, none.

Phenolsulphonephthalein Test for Renal Function. After the patient has emptied the bladder, he is given 8 oz. of water to drink. Using a 1 c.c. Luer syringe, 1 c.c. of phenolsulphonephthalein (supplied ready for use in ampules) is injected into the cubital vein of the arm, or into the gluteal region intramuscularly. Exactly one hour

later, the patient voids. He is given two glasses of water to drink at this time. One hour after this, he again voids. Both specimens are alkalinized with 10 per cent sodium hydrate solution and the volume is brought up to 1000 c.c. with tap water. The percentage of dye is estimated in the colorimeter. If the injection is intramuscular, the urine specimens should be collected one hour and fifteen minutes and two hours and fifteen minutes later.

Carbon-dioxide Combining Power of Blood. The estimation of the carbon-dioxide combining power of the blood can be done easily by means of the portable apparatus recently described by Fradkin,¹ full directions accompanying the apparatus.

Sedimentation Time of Blood. The sedimentation time of the blood is estimated by drawing blood from a Luer syringe up to the 1 c.c. marked in a tuberculin syringe which has previously been charged with 0.2 c.c. of 5 per cent sodium citrate solution. The contents are then expelled into the sedimentation tube designed for that purpose. Readings are recorded when the red blood cell column reaches the 16 mm. mark. Normally this occurs within about an hour.

Iso-agglutination and Mutual Match for Transfusion. For the determination of the blood group, it is necessary to be provided with serum from a group A(II) and group B(III) individual. On an ordinary slide place separately a drop each of group A and group B serum. To each drop add 1 of the blood of the individual to be tested and mix. Examine after five minutes under the low power microscope. If the red cells are clumped only with the group A serum, the blood is that of a group B individual. If the cells are clumped by the group B serum, the individual belongs to Group A. If the cells are clumped by neither, the individual belongs to Group O. If the cells are clumped by both, the individual belongs to group AB. In the latter instance, auto-agglutination must be ex-

¹ *Lab. & Clin. Med.*, 14: 973, 1929.

cluded. By observing the individual's blood cells without the addition of serum, if there is no clumping, auto-agglutination can be excluded.

For Cross Matching. Into a white blood cell pipette aspirate 3 per cent sodium citrate solution up to 0.5 mark. Fill the pipette with blood of the recipient up to the 11 mark, mix and expel all but the contents of the capillary portion of the tube up to the 1 mark, into a $3 \times \frac{3}{8}$ in. test tube. Expel the remainder into a

similar tube. Expel all the contents of pipette excepting that in the capillary pipette up to the 1 mark, into recipient tube containing the smaller portion of the blood. Expel the remainder of the contents of the pipette into the test tube containing the larger portion of the recipient's blood. Shake both tubes thoroughly. Let stand for ten minutes and on a slide observe under the low power microscope. If there are no clumping in either, the bloods are compatible.

OFFICE TREATMENT OF URINARY TRACT IN WOMEN*

H. DAWSON FURNISS, M.D., F.A.C.S.

NEW YORK

IN THE consideration of the scope of office treatment of bladder, urethral, ureteral, and kidney conditions, one must take into account the magnitude of the procedure, the tolerance of the patient for the treatment itself and the reaction. Also the care she may have after leaving the office. What is well borne by one patient would prove impossible for another. If there is any doubt as to the reaction the patient may experience, the first treatment should be given in the hospital; the reaction to this will serve as a guide to subsequent care.

The patient should be cautioned as to any possible disagreeable after-effects, and instructed as to what to do should they occur. Means of relief, rather than a prescription, should be given, thus avoiding unnecessary suffering while waiting for the medication.

A large part of the office work in urological conditions relates to diagnosis, but this does not fall within the scope of this paper. The subject will be discussed in relation to the kidneys, ureters, bladder, and urethra.

KIDNEYS

Office treatment of the kidneys is restricted to pyelitis, and stricture of the ureter at the ureteropelvic junction. Dilatation of the stricture at this point can be well carried out in the office, if previous dilatation in the hospital has not been attended by too marked a reaction. For the renal infections, lavage may be as well done in the office as in the hospital, provided ureteral drainage is competent and the condition is not acute. Kidney lavage is not apt to be attended by disagreeable reaction. My best results have been with nitrate of silver, though in the instances where there is moderate hydronephrosis, a water-soluble substance, such as mercurochrome, which does not produce a precipitate with the urine, is in order. It is, of course, understood that a thorough diagnosis has been made and that one is dealing with a simple pyelitis, and not a kidney stone or tuberculosis.

URETERS

Conditions most frequently requiring attention are ureteral strictures, calculi,

* Submitted for publication December 24, 1929.

and intravesical ballooning of the ureter with narrowed orifices.

Strictures. The first dilatation should preferably be in a hospital, although it may be performed in the patient's home, or even in the office if the patient is within easy reach of home. Often there is quite a reaction, and the patient may develop acute retention in the ureter and the kidney pelvis from ureter blockage due to the swelling of the ureteral mucosa following instrumentation. This is not so apt to occur in subsequent dilatations. Dilatation should be done in a gradual manner, and no attempt should be made to reach the maximum at one treatment. By using dilators of an increasingly larger caliber, at intervals of four to seven days, the dilatation may be carried up to 9, 10, or even 14 F., with little or no reaction and only slight discomfort. Until one sees what reaction is experienced the patient is directed to go to bed, apply heat for pain, and to have codeine, or if necessary, morphine, in doses sufficient to relieve.

Stone. This is usually best treated in the hospital, though occasionally it is justifiable to pass a catheter or bougie as an office measure, to change the position of the stone, to loosen it when adherent, or to dilate the ureter below the stone. While I have fulgurated the mucosa over a stone impacted in the lower end of the ureter, in the office, I feel it is a bit too much except in cases of phlegmatic individuals who tolerate pain well. It is difficult to get anesthesia by any of the methods that can well be considered office procedure. The same applies to the cutting or fulguration of the ureter that balloons intravesically.

BLADDER

The most usual condition encountered here is inflammation. While many feel that bladder inflammation is nearly always associated with renal infection, urethral obstruction, or foreign bodies, I am convinced that most of the bladder infections

which come under my observation are primary in the bladder and not complicated with obstruction or kidney infection. For these, lavage with boracic acid solution, followed by the installation of argyrol, combined with urinary antiseptics, gives good results. Rest in bed is important though not absolutely essential. Hot vaginal douches often afford relief. For the first few days a sedative, such as tincture of hyoscyamus with potassium citrate, is given. Of the urinary antiseptics, urotropine and pyridium have been the most effective I have found. Except with an alkaline urine, the acid sodium phosphate should not be given with the urotropine, as it sometimes produces a very marked irritation and an exaggeration of the cystitis. Frequently hematuria, of vesical (or renal) origin, is produced. In some of the more stubborn cases silver nitrate, 1:10,000 to 1:2,000 is more effective than the argyrol.

The Hunner type of ulcer is best treated in the hospital by fulguration under spinal anesthesia, with subsequent office treatments consisting of the installation of argyrol, rivanol 1:5,000, or nitrate of silver 1:500. Some of the more simple ulcers may be sufficiently anesthetized with 5 per cent cocaine, to lightly fulgurate or to touch with silver nitrate stick, with patient in knee-chest posture.

Small foreign bodies may be removed either through the water type of cystoscope or the Kelly endoscope.

Certain papillomata may be fulgurated with little discomfort. There is almost no pain to this procedure until the base and the vesical wall are treated. If the growths are large or numerous, the fulguration is more satisfactorily done in a hospital with the patient anesthetized.

The most frequent, and one of the most troublesome, conditions encountered is cystitis coli, or inflammation localized in the trigonal area, often extending into the urethra. This is best treated by urethral dilatation to 30 or 35 F. and applications of 5 to 10 per cent silver nitrate to the trigonum and urethra,

through a Kelly endoscope with the patient in the knee-chest posture. Previous applications of cocaine to the urethra and bladder makes this only slightly uncomfortable. The reaction is not often of any great moment; though there may be urgency and frequency for an hour or more. This treatment may be given every five to seven days.

URETHRA

Urethritis, stricture, papillomata, caruncles, and skenitis may all be treated in the office.

Urethritis. Acute urethritis is most often due to the gonococcus. In the acute stage of the infection rest, alkalies by mouth, and hot vaginal douches are indicated. After the condition subsides to some extent, argyrol is injected once or twice daily. When it is impracticable for the patients to come to the office for these treatments they have been instructed in the injecting of the argyrol themselves. It is not a difficult procedure for them and I have seen no harm result. The condition has cleared up much more rapidly with the frequent treatments. In chronic urethritis the best results have been obtained by the application of 5 to 10 per cent nitrate of silver through a Kelly endoscope, with the patient in knee-chest position. If there is any evidence of urethral stricture, the urethra should be dilated to 35 to 37 F. Treatments are given every five to seven days. A cystitis coli, or trigonitis, is often present at the same time and should be treated with applications of silver to the trigonal area.

Skenitis is a frequent accompaniment of urethritis and usually clears up as the urethritis improves; but at times the infection becomes chronic in the glands and their ducts. With a suitable speculum (skenoscope) and a small probe-pointed cannula these ducts may be injected with

an antiseptic solution. Argyrol works well if the infection is not of too long standing. If a destructive action is desired strong silver nitrate or carbolic acid may be used. Some may require incision and the application of pure silver nitrate, or the galvanocautery. Electrocoagulation may be used but the degree of destruction is difficult to determine and may result in too much tissue being destroyed.

Papillomata. These are not uncommon in the urethra and should be fulgurated through one of the modifications of the Kelly endoscope with the patient in the knee-chest posture. Cocaine anesthesia, brought about by the application of a 5 per cent solution of cocaine, is usually sufficient.

Stricture. While not as frequent as in the male, more cases are encountered than is usually thought. Many are of large caliber, and while not usually sufficient to cause retention of urine, often interfere with the healing of a chronic urethritis. They may be detected with a bougie a boule. Often there is a contracture of the external meatus, especially in older women. Rarely does one meet a tight, fibrous stricture. Except for those at the external meatus, dilatation, done gradually, and at a number of sittings, is sufficient. There is a tendency to recontraction and repeated dilatations at intervals of 2 to 6 months may be necessary. For the contracted, external meatus, incision, under infiltration anesthesia, may be required.

Caruncles. These are best removed by the Oudin or desiccating current. For large ones, where deeper destruction of tissue is required, carefully controlled electrocoagulation may be indicated.

Again I wish to emphasize that while many procedures are possible in the office, only those which can be well tolerated by the patient should be done; also that provision be made for any reaction which may occur as a result of treatment.

SURGICAL CONDITIONS OF THE EYE*

WILLIAM L. BENEDICT, M.D.

ROCHESTER, MINNESOTA

SURGICAL treatment of conditions of the eye can be employed safely in office practice if precaution against infection is used. Asepticism, as it is employed in modern operating rooms, should also be used in office practice rather than antisepticism; this will permit uninterrupted healing of wounds. Antiseptics in mild solutions do not materially interfere with healing of clean wounds and sometimes the use of strong solutions, topically applied, prevents the spread of infection from wounds that cannot otherwise be made surgically clean, without delaying healing further than the time necessary for the sloughing of necrosed tissue. As a false sense of security may be engendered by faith in the antiseptic properties of solutions usually employed in ophthalmic surgery, they may better be used sparingly, and as adjuncts, rather than as primary agents. A high degree of asepsis can be attained by copious irrigation of the eye with neutral, or slightly alkaline, solutions so that minor injuries and small surgical wounds can be adequately cared for. The skin and conjunctiva naturally harbor organisms, most of which are not pathogenic and do not penetrate the epithelial layers. Such organisms are easily caught in the mucous secretion of an irritated or inflamed eye and are carried away with the secretion. A convenient method of irrigating the eye in office practice is by a solution of boric acid in a common wash bottle which can be sterilized daily and can be kept filled with a freshly prepared and sterilized solution.

The conditions of the eye for which surgical treatment can be used affect the lids, conjunctiva, lacrimal apparatus, and cornea, in the relative frequency of the order in which they are named. In industrial practice, in which eye hazards are

increased by exposure to injury by fragments of metal and of wood, affections of the cornea are, of course, more common. But most of such corneal lesions are minor and do not require procedures that would be classified as surgical.

AFFECTIONS OF THE LIDS

Sty and Chalazion. The common sty, an inflammation of one or more of the sebaceous glands of the eyelid, is the most frequent condition of the lid which one is called on to treat. The onset is insidious, with edema, and tenderness of the lid; a sensation of foreign body in the eye is the chief complaint. The appearance of the lid is characteristic. There is a center about which the swelling occurs, usually pointing early in the course of the inflammation to the gland affected. The swelling of the lid is not uniform, differing thereby from the swelling seen in deep-seated conditions of the eye or orbit, or in constitutional disorders. Several glands may be affected at one time, with marked swelling and tenderness of the lid, and even with fever with toxic symptoms. The confluence of several purulent pockets may spread to cellulitis of the lid, with marked infiltration of the deeper structures of the orbit. More often, however, the affection is seen as multiple styes recurring along the margin of the upper and lower lids, first on one eye, then on the other, sometimes continuing for several months in spite of treatment.

Medical treatment of styes will not be considered in this article, but it must be made clear that the sty is an acute inflammation and should be treated as such to prepare the way for operative procedures if such should become necessary.

Not often does the infection extend beyond the lid. Complications are rare.

* Submitted for publication December 24, 1929.

Usually the gland breaks down and a purulent cyst will point at the margin of the lid. Spontaneous rupture will be followed by prompt healing, without a visible scar. However, indolent stys occur that do not rupture spontaneously, but remain as cystic swellings. Edema and tenderness may not have been noticeable. After several weeks the tumor may disappear, leaving a small, cord-like, palpable body, or it may remain for months without noticeable change. Such a lesion is usually referred to as a chalazion.

During the acute stage of inflammation a sty should not be opened. It is contrary to good surgical practice to open into a region of acute inflammation. Under normal conditions an abscess with a protective wall will form, which will open spontaneously or which may be opened into or excised. The more acute stys should be allowed to run their course with non-surgical interference. After the subsidence of the inflammation, if a cyst or pocket of pus remains, as a chalazion, it should be removed.

When the swelling of the lid due to acute inflammation has subsided, the chalazion may be felt as a mass in the lid. From the conjunctival side it can be seen as a round, loosely attached body if it is in the lower lid; if in the upper lid, it appears as a discolored streak in the tarsus. A large chalazion may be present beneath the skin of the lid as well as on the conjunctival side. A chalazion should be removed, however, from the conjunctival side. Complete anesthesia can be produced by the hypodermic injection of 15 minims of a 2 per cent solution of procaine. This solution can be had in ampules of convenient size, sterilized and ready for use. The lid should be everted and firmly held in chalazion forceps. The incision should be made along the line followed by the cyst. In the case of deep conjunctival cysts in the culdesac, the incision should be in the direction of the fold, whereas to open a cyst in the tarsal plate of either the upper or lower lid, the incision

should run perpendicular to the margin of the lid. The incision should be long enough to permit free inspection of the inside of the cyst. The walls should be curretted, then swabbed with a caustic agent, such as zinc chloride, silver nitrate, or phenol and alcohol. After further copious irrigation with boric acid solution a bandage should be applied with light pressure to prevent bleeding.

Ectropion and Entropion. Ectropion of the lower lid, with hypertrophic conjunctivitis, may often be satisfactorily corrected by cautery puncture, after the method described by Ziegler. Simple excision in hypertrophic conjunctiva is followed by irregular contraction, that shortens the lid between the canthi, and only in exceptional instances should it be done. Surgical procedures for correction of ectropion other than use of the actual cautery, call for more extensive work than should be attempted outside of a well equipped operating room. Entropion of the lid is more frequently brought to the attention because of contracting bands in the culdesac, following chronic conjunctivitis or injury. The normal secretion of the conjunctiva is replaced by a thick mucous discharge which rolls into long strings that sweep about over the eye, causing great annoyance and discomfort. The lashes come in contact with the cornea, producing superficial keratitis which in turn stimulates further congestion and lacerimation.

Bands and Contractures. Bands or adhesions varying from only slight contraction in the culdesac to pseudopterygium and symblepharon are of common occurrence. If they result from chronic trachoma, xerophthalmia, pemphigus, or membranous conjunctivitis, the entire conjunctiva may be so changed that repair can be made only through replacement by skin or mucous membrane from some other part of the body. Simple division of conjunctival bands and adhesions is a common office practice that is mentioned only to be condemned. Stretching of bands, or the insertion of plates of wax

or metal after division, only leads to more firm contraction and increases the severity of the symptoms. Contracting sockets following enucleation are sometimes filled with gauze or a large artificial eye in an attempt to enlarge it. The result is always disappointing and increases the difficulties to be overcome in an operation later. The correction of contracted sockets or contracted culdesacs is a procedure that should not be carried out in the office.

Biopsy. If properly done, there is little harm at any time in taking tissue from the conjunctiva or lid for biopsy. Probably the greatest error in taking tissue for biopsy lies in taking too little. The pathologist must see the entire lesion if he is to give the most valuable diagnosis. Entire chalazions may be excised without deformity of the lid. Recurrent chalazion should arouse the suspicion that a malignant condition is present and it warrants complete excision of the growth for pathologic examination. The same holds true for recurrent growths about the limbus. A well developed epithelioma of the cornea or conjunctiva, at the limbus, may occur within three weeks from the onset of the first symptom. An effective method for removing limbal growths is through use of the electric cautery. However, the histologic pathology of growths in this region should be known; therefore it is advisable to excise them under local anesthesia before applying the cautery. To remove growths at the limbus, a sharp scalpel should be used. Beginning on the corneal side, the entire growth often can be shaved off and preserved for pathologic study. The denuded area should then be lightly cauterized with an actual cautery and the eye should be closed with a quantity of White's ointment placed under the lid. Any growth worth removing from the eye is worth pathologic examination. Epithelioma at the limbus frequently is not diagnosed; yet it is not infrequently seen. Radium and roentgen rays are of value after the growth has been removed surgically.

AFFECTIONS OF THE LACRIMAL APPARATUS

Lacrimation varies with reflex irritation of the eye, and the freedom with which tears can escape through the nasolacrimal duct. Interference with the escape of tears may be brought about by inversion of the lid, so that the puncti rest flatly against the ocular conjunctiva, occluding the canaliculi. With winking of the lids and movement of the globes there is a drawing upward of the secretion from the nasolacrimal duct, through the puncti, because of the valve-like action when the puncti lie flatly against the conjunctiva. Tears will not escape through the canaliculi when the puncti are in this position. Consequently, there is a collection of lacrimal fluid mixed with secretion from the sac, flooding the eye, frequently giving rise to troublesome conjunctivitis. Occasionally, atresia of the puncti also is present. Usually there is less conjunctivitis with atresia of the punctum than is found with a wide punctum that is turned inward against the globe. The difference in irritation can be accounted for by the absence of secretion pumped up from the lacrimal sac. To remedy either condition, it is necessary to establish free drainage for tears through the nasolacrimal duct. After a few drops of cocaine or butyn solution have been instilled, the lacrimal apparatus should be sounded very carefully by a No. 1 or 2 silver Bowman probe. Great care should be taken not to injure the punctum or the lining of the lacrimal sac. If the only obstruction found is in the punctum or canaliculus this may be corrected by simply dilating the punctum a few times, or by slitting the lower canaliculus with an Agnew knife, after the method of Stilling. The necessity for opening the canaliculus is in the minds of most practitioners, very seldom encountered.

The beneficial effect of such operations can be augmented by frequent irrigation of the culdesac and instillation of a mild alkaline lotion, consisting of zinc salicylate, 1 grain to the ounce of saturated solution of

boric acid. A few drops of solution of epinephrine may be added to the collyrium according to the wishes of the surgeon. In more protracted cases, lachrimation and conjunctivitis are the results of occlusion or stenosis of the lower portion of the lacrimal duct. Exploration of the duct with a small sound usually will reveal the situation of the first obstruction below the sac. In infants, it is usually necessary only to push the probe on into the nose to secure adequate drainage. Rapid dilatation of the duct with the use of large probes is successful in some cases, but more often disappointing in its results. The procedure is painful, as it is rather difficult to secure adequate anesthesia by topical applications. If large probes are to be used the procedure should be done under general anesthesia and would better be done in a well equipped operating room. Operations for the relief of dacryostenosis, other than sounding the duct, are hospital procedures. The safety of the eye and comfort of the patient should be the first concern in the treatment of lacrimal stenosis. Many patients who now seek relief for dacryostenosis have had the lacrimal duct probed many times with no benefit. The lining of the nasolacrimal duct is abundant, hanging in folds, and contains many pockets through which a

false opening could easily be made if force were used in exploring for obstruction.

A conservative procedure consists in injecting a few minims of procaine into the lacrimal sac, bringing about analgesia without complete anesthesia. A small probe can then be manipulated in the duct without pain unless undue pressure is used. The patient can then indicate to the surgeon whether the probe is going through the sac, whereupon it should be withdrawn. This procedure may be repeated daily for a week or two. If the duct cannot be opened easily a more radical operation should be adopted. Cellulitis of the face often follows the passage of a probe through the wall of the sac; so great caution should be exercised in probing the duct. Only those who are thoroughly familiar with the use of such probes should undertake to dilate a stenosed duct.

GENERAL COMMENT

The practice of office surgery of conditions of the eye should always be conservative. Unless some evident benefit is to be derived from a surgical procedure, one should refrain from attempting operations that cannot be completely carried out under conditions as satisfactory as those which could be obtained in an operating room.

BLEEDING FROM THE VAGINA *

MERVYN V. ARMSTRONG, M.D., F.A.C.S

BROOKLYN, N. Y.

IN this age of modern hospital facilities, it would seem as though most cases of bleeding from the vagina should be sent to institutions for treatment. This is true in most urban communities. Nevertheless a considerable proportion of cases receive some form of treatment before arriving at the hospital and this treatment is instituted either at the home of the patient or in the physician's office.

Anyone who has had even a moderate experience on the gynecological services in hospitals in the larger cities, cannot fail to be impressed by the inadequacy of vaginal packing as performed by the casual practitioner. In most instances the tampon consists of a piece of plain bandage gauze about one yard long which is floating about in the vagina and serving no function except as a possible source of infection.

* Submitted for publication October 16, 1929.

In cases of incomplete abortion, hydatidiform mole, uterine fibroids or polyps, fibrosis uteri, malignant disease of the uterus (either fundal or cervical), endometrial hyperplasia, and the hemorrhages associated with the latter months of pregnancy, i.e., placenta previa and premature separation of the normally implanted placenta, the hemorrhage may be so alarming as to cause the practitioner to consider immediate packing of the vagina.

At the Long Island College Hospital, we have been trying, for some time past, to impress our students with the fact that in cases of placenta previa and premature separation of the normally implanted placenta, the diagnosis should be made on the history and abdominal findings alone, and that a vaginal examination is not necessary and most certainly not beneficial; and that vaginal packing is contraindicated. We feel that nothing is to be gained by these procedures, and if they are done, they transform a clean case into a potentially infected one. Thus they interfere with the possibility of delivery by cesarean section, if such a procedure is considered.

It is well to keep in mind Cullen's classification of vaginal bleeding when in attendance on a case of this kind: (1) bleeding associated with pregnancy: abortion, ectopic, gestation, hydatidiform mole, retained secundines, chorio-epithelioma, placenta previa, premature separation of the normally implanted placenta; (2) constitutional causes: endocrine dyscrasias, etc.; (3) bleeding *not* associated with the pregnant state: cervical or fundal polyps, endometrial hyperplasias, cervical block, malignant or non-malignant tumors.

If the bleeding is due to causes other than those of placenta previa or premature separation of the placenta, and is severe enough to warrant immediate packing the technic should be as follows:

The patient should be placed in either the genupectoral (knee chest) or Sim's left latero-prone position. The vagina cannot be properly packed with the patient in the dorsal or supine position.

The operator should then encase his hands in sterile rubber gloves (preceded by surgical preparation of the hands if facilities are present).

A sterile Sim's speculum should then be introduced into the vagina. (The Graves bi-valve speculum is of little value in vaginal packing unless it is opened and transformed into a modified Sim's instrument.)

The cervix and vaginal vault is then painted with Tr. iodine or 4 per cent mercurochrome solution applied by means of sterile cotton pledgets about the size of a walnut, held by a sterile sponge stick holder.

Two-inch sterile vaginal packing gauze in the form of a roll should be used. It should be immersed in either normal saline solution or 4 per cent solution of mercurochrome. The gauze must be moist. One end of the roll is grasped by means of a sterile uterine dressing forceps. The roll is held in one hand and unrolled as it is fed into the vagina through the speculum. The first portion of the moistened gauze is placed against the external os of the cervix, then the vaginal fornices are packed. The packing is continued until the vagina is filled to capacity. The amount of gauze used depends on the size of the vagina, but in general it may be said that unless at least 5 yards have been used the packing is inadequate. Some cases take as much as 10 yards.

Vaginal packing should never be left in situ for more than forty-eight hours. Its removal should be gradual, beginning with a few inches at the end of twenty-four hours until it has all been removed.

VARICOSE VEINS: THEIR CAUSE AND TREATMENT*

WILLIAM H. BARNES, M.D.

OAKLAND, CALIF.

MANKIND has been afflicted with varicose veins since time immemorial. These afflictions have caused considerable discomfort and inconvenience to some while others have suffered only slightly. Various forms of treatment have been resorted to with numerous good and bad results.

Varicose veins and their relation to varicose ulcers were early referred to by Hippocrates, Galen, Paré, Hunter and Valsalva. Several of these noted men made special studies of the ailment. Hunter and Valsalva were among the first proponents of the theory that stagnation of blood in the veins of the legs was the pathogenic cause of varicose ulcers.

ETIOLOGY

Among the most frequent causes conceived for the formation of varicose veins are weakened walls as shown by congenital abnormalities or bodily weakness derived through other depleting conditions, infectious emboli associated with a low-grade symptomless phlebitis, endocrine disturbances, stasis due to strenuous strenuous physical occupations, tight garters, etc. Pelvic pressure caused by such factors as pregnancy and tumors is also one of the chief etiological factors. Kashi-mure, a Japanese surgeon, believes that loss of nervimuscular tone is one of the important causes. It is not inconceivable that several of these factors in the same person may account for the varices found among many of our patients.

PATHOLOGY

The pathology of this aggravating condition has been described by many, of whom McPheeters has given one of the best descriptions. Most of the venous blood of the leg normally flows upward

through two sets of veins, the deep and superficial saphenous. The deep veins are supported by muscle and fascia and seldom have varicosities. The superficial veins have little support except their thin walls and the overlying skin. Both have valves supporting their respective columns of blood.

Due to the causes already enumerated the weakened walls of the veins give way. The valves, unable to support the extra column of blood, allow a backflow. Dilatation, distention, sacculatation and elongation are the results. They have been classified into four different sizes: (1) up to 0.5 cm.; (2) 0.5 cm. to 1 cm.; (3) 1 cm. to 1.5 cm., and (4) 1.5 cm. to 2 or more cm. Those larger than 2 cm. in diameter are generally saccular and aneurysmal in type.

Much discussion has been carried on regarding the direction of the flow of blood in cases of varicose veins. It has been shown under the fluoroscope that when 1 c.c. of lipiodol was injected near the outlet of the long saphenous vein it was forced by muscular pressure to below the knee, thence through the communicating veins to the deep saphenous vein. Muscular action of the toes and ankle caused a fluctuation in the deep saphenous vein while by pushing the toes against a solid object the blood would flow upward into the iliac veins. None flowed upward through the superficial saphenous vein. This shows therefore that the flow of blood in varicose veins of the leg is practically stationary or reversed, flowing from the superficial to the deep through the communicating veins.

SYMPTOMS

The symptoms of this unpleasant condition, such as early fatigue in walking or standing, cramps in the legs, severe pain where there is a phlebitis or periphlebitis,

*From the Surgical Clinic of the Oakland Health Center, Oakland, California. Submitted for publication September 9, 1929.

depends upon the degree of incompetency of the veins. If ulcers are present serious hemorrhages may take place.

FIG. 1. Legs of patient before injection. Left leg (No. 2) shows dilated vein beginning at edge of ulcer and extending nearly to knee. Leg No. 1 was very similar to left.

DIAGNOSIS

The degree of varicose involvement must be determined by a very careful examination. Not only must the circulation of the extremity be accurately determined but the patient's general condition, especially in relation to his circulation and kidney function, requires a careful study. Cardiac decompensation with hypertension needs careful checking up, also cases with acute or chronic nephritis and diabetes. The main fact to be determined relating to the circulation of the extremity is the patency of the communicating and deep veins. Pratt's method is probably one of the best and most recent tests. He applies an ace bandage around the leg below the

saphenous opening sufficiently tight to prevent circulation in the superficial veins. If after walking 10 blocks there is no pain in the leg the deep veins are considered to be functioning normally. Phlebitis and periphlebitis must be ruled out as tested by looking for painful areas on pressure and pain experienced by the patient on walking.

TREATMENT

Having ruled out such complications as have been mentioned one can then proceed with the treatment. The history of the injection treatment dates back to the invention of the hypodermic syringe by Pravaz in 1851. Attempts were made to obliterate the veins by perivenous and intravenous injections. Alcohol, phenol, ergotin and other chemicals were used but were soon discontinued because of the disastrous results from infections, hemorrhages and emboli. Linser and Zirn (1916) noticed the hardening results to veins from the intravenous use of bichloride of mercury in treating lues. Frequent cases of mercurial poisoning resulted but stimulated research for a non-toxic solution that would cause a permanent thrombus. To this end they found that 20 per cent sodium chloride was a good substitute for mercury in obliterating veins. Sicard and Forestier noticed during the war that alkaline solutions produced hardening of the veins. They used sodium carbonate but this was too caustic and they were obliged to discontinue its use. Later they used sodium salicylate with much more satisfaction, but found that in an occasional case it caused severe toxic symptoms. Noble of Germany is a strong advocate of invert sugar solution while in England quinine and urethane preparations are popular. McPheeters has used sodium salicylate, sodium chloride and sugar solutions with excellent results. Sodium salicylate is an excellent drug but an injection of a small amount, 1 to 2 c.c., is necessary to test out the liability of its specific toxicity to the patient.

Considerable discussion has been in

vogue of late as to the advantages of the injection treatment over the surgical removal of the defective veins. It would

of a thrombus. Statistics show that this is more theoretical than real, only 4 authoritative cases thus far having been

FIG. 2.

FIG. 3.

FIG. 4.

FIG. 2. Part of right leg with eczematous area under which was large dilated saccular type of varicose vein.

FIG. 3. Needle inserted in vein with syringe containing injecting solution.

FIG. 4. Empty syringe after injection. Above point of injection is a rubber tourniquet tied lightly around leg. This is immediately released following injection.

seem, according to the recent literature, that the injection treatment, causing a definite injury to the venous walls, a permanent thrombosis and final obliteration of the veins, is the method of choice. Statistics show that the risk from surgical removal is 1 in 250 while with the injection treatment it is 1 in 5000. The objections to operative risk are:

1. The more frequent occurrence of fatal emboli.
2. Recurrence of varices in the communicating veins sometimes extending across the area of removal to the communicating vein on the opposite side.
3. Unsightly scars.
4. Confinement of the patient from three to six weeks, a very important economical factor.
5. The danger from postoperative infections.

The chief objection to the injection treatment is the theoretical formation of an embolism secondary to the formation

reported in the literature. McPheeters reports a case of a patient suddenly dropping dead ten days after an injection treatment. Autopsy showed a recent thrombus in the orifice of the pulmonary artery. Examination of the injected veins showed well-formed thrombi.

REPORT OF CASES

I wish to report results of the injection treatment on 20 cases. Five cases had an involvement of both legs. Three cases were males, the remaining women. Two women were under thirty-five, the remaining patients between forty and sixty years of age. Trendelenburg tests were made before injections were begun. One complication resulted. Some of the solution (sodium salicylate in this case) leaked out through the puncture opening of the thin veined walls in a man aged sixty. A small slough resulted, taking two months to heal, but the results to the vein were excellent. All the other patients were

cured of their varicose veins with no recurrences. Several had swollen and tender legs for about two weeks after treatment due to the chemical phlebitis produced by the injections. According to the many workers this counts for a favorable result. The solutions used were sodium chloride 20 per cent for 8 patients and sodium salicylate 40 per cent for 12 patients. A Luer syringe with 26 gauge needle was used. The amount injected was a variable factor, depending upon the size of the vein. The injections of sodium chloride varies from 3 to 8 c.c. per vein while those made with sodium salicylate ran from 2 to 5 c.c. One leg at a time was usually injected, with a tourniquet above the beginning of the varicosity. All patients were treated in sitting posture. All patients complained of a stinging pain lasting five to ten minutes in the leg at and below the point of injection. The sodium salicylate produced a more severe pain than the sodium chloride. All patients were allowed to be upon their feet daily.

COURSE

Immediately after injection the vein becomes hardened and the tortuosity changes into a straighter line. After a few hours the skin over the injected area takes on a bluish or copper color which lasts for several days. Patients should be warned against bumping their legs during the time the organization is going on. It tends to cause injury to the thrombosed vein wall, pain in the injured leg and prolongs recovery. Swelling of the leg is apt to occur, due to the phlebitis of the communicating as well as the injected veins and lasts two to three weeks. Occasionally some of the injected solution will leak out of the thin punctured venous wall, resulting in a slight infiltration of the surrounding tissues, or the solution may be injected

outside of the vein. Both of these procedures cause a slough painful and slow in healing. They are best treated by further infiltration of the area with normal saline solution, reducing the concentration of the previously injected solution. Two months are often required for sloughs to heal.

Several investigators, both American and European, have reported upon the histological changes in veins. All agree that the chemicals injected injure the intima, allowing an infiltration into the venous wall. Fibrous tissue develops from the proliferating connective tissue of the venous walls, red and white blood cells are deposited and a firm thrombus results. Organization takes place during the next few weeks and a fibrous cord is the result, thus giving relief from symptoms and a better looking leg to the patient.

SUMMARY AND CONCLUSION

1. A careful physical examination is necessary before any treatment is commenced for varicose veins.
2. Patency of the deep veins must be definitely established.
3. Phlebitis and cardiac defects, nephritis and diabetes are contraindications to either surgical or injection treatment of varicose veins.
4. Any treatment must aim to obliterate the superficial vein and utilize the deep vein for the functioning one.
5. Surgical operations have been less successful than the injection treatment. They often result in recurrences, sloughing, infections and bad looking scars, and prevent the patient from working from three to six weeks.
6. The injection treatment for varicose veins seldom interferes with the occupation of the patient and gives the best permanent result.

INFECTION OF HAND & FINGERS*

CARL BECK, M.D.

CHICAGO

CONSIDERING the fact that the hand comes in contact with contaminated objects more than any other part of the body, and that the fingers are exposed to more injuries than any other organ, it is remarkable that infections of the hand and fingers are not more common than they really are. They belong, nevertheless, to the most frequent pathological conditions the general practitioner is called upon to treat.

PATHOLOGY

Infections of hand and fingers are due to the entrance of microorganisms through wounds, among which the punctured wounds play the most important rôle. And here again it is the volar surface of the hand and fingers which is more apt to be infected and where infection is of greater danger, owing to the predisposing histological structure of the skin of this surface. When a sharp instrument or sharp body makes a puncture on the soft part of the skin of the dorsum an ensuing infection

will meet a pliable skin yielding readily to the formation of an abscess. But when the inner surface of the fingers or hand is punctured and infected, the skin, being of a tougher character and the underlying fat of coarser structure, does not yield and hence the infection penetrates into the deep tissues. This endangers the vitality of the deeper structures and leads to all kinds of complications. It is important, therefore, that punctured wounds and small cuts of the volar surface always be regarded with suspicion, and treated with a presumption that they are apt to be infected more than those of other parts of the hand. Another peculiarity of infections of hand and fingers, again referable to an anatomical peculiarity, is that the wound infections of the dorsal surface are apt to lead to rapid propagation through the lymph channels in the form of lymphangitis, while the infections of the volar surface are more apt to be localized and restricted to the phalanges as so-called felons, or to the palm as abscesses within

* Submitted for publication November 19, 1929.

the tendon sheaths, intercommunicating with joints or other structures. The infecting microorganisms are either streptococci, staphylococci or other pus-forming microorganisms which enter the tissues of the fingers or hand through punctured wounds with or without a foreign body, such as a small sliver, splinter, a piece of cloth, or other material.

SYMPTOMS

The symptoms of infection may be clear and manifest or they may be very obscure and misleading. As a rule the focal symptoms predominate and lead the physician to an early diagnosis. The local signs of inflammation: heat, swelling, tenderness, redness, as well as a throbbing of the part, will make an early diagnosis of acute infection very probable. The general symptoms are those common to all other infections, namely chills, fever, general malaise, headaches, rapid pulse, etc. However if the infection has lasted for some time these acute symptoms may subside or may become very insignificant. The acute infection usually turns into a sub-acute one and may lead to a chronic infection, which is characterized by a different symptomatology, namely: the formation of exudate and localized death of tissues or necrosis. The exudate is as a rule purulent. The tissue underneath the tough skin is melting away into a debris consisting of pus and blood, and structures like tendon and bone which have only a meager circulation easily die off, becoming entirely deprived of nutrition because of the thrombosis of the blood vessels and the pressure of the exudate. These abscesses follow predisposing channels along the sides of the tendon sheaths and in many instances lead to their necrosis. This is a very important complication as it has its effect upon the function and the use of the hand. Once established, such an abscess of the tendon sheath is apt to push forward into the palm of the hand, destroying the tendon and perforating into the loose tissue of the dorsal surface, thus

circulating the pus into important structures of the hand and leading to destruction of various kinds with contracture or stiffness as common sequelae.

The symptoms of abscess are in many instances characteristic. Fluctuation shows the presence of liquid exudates. Edema is strongly indicative of deep suppuration. Besides the tendon, the bones are very often exposed to the effect of pus. The periosteum is one of the structures which are easily infected through propagation of the process, and a subperiosteal abscess lifts the periosteum from the bone, depriving the bone of its nutrition. This results in an osteitis and osteomyelitis followed by partial or total necrosis of the bone (sequestrum formation).

One of the most dangerous complications is that of infection reaching the capsule of the phalangeal joints and the joints themselves. While we are capable of dealing favorably with the other complications, this one inevitably destroys the function of the joints by leading to a necrosis of the cartilage, which is very poorly nourished by the surrounding blood supply. Fortunately the capsules of the larger joints are very resistant to the acute infection, and as a rule only the small joints suffer in this manner.

DIAGNOSIS

The diagnosis is made from the symptoms already mentioned. The x-ray is a very valuable asset in clinching the diagnosis of infections. While inflamed structures do not show any special shadows, the inflammations change the structures of the bone to such an extent that the trained eye of the roentgenologist easily detects the presence of osteomyelitis, osteitis and periostitis. The shadows and the structure of normal bone disappear and the irregular, transparent shadows of the diseased bone take their place. The sequestrum becomes visible. One of the most characteristic symptoms of this infection is the appearance of pus, which by breaking down the tissues forms a

fistula from which it escapes. As soon as this stage is reached, either spontaneously or through the interference of the doctor cutting into the abscess, the general symptoms usually disappear and the acute infection turns into the subacute, chronic stage.

COURSE AND RESULTS

There are hundreds of possibilities following infections of the hand, many depending upon their management and treatment. General sepsis and fatalities are rare. Spontaneously and unaided by the physician many infections yield excellent results, even if treated only by home remedies such as poultices. The infection leads to an abscess, which ripens and breaks through, emptying the pus, and then heals up without leaving a trace behind except a tiny scar. There are other instances in which treatment begins too late. Complications will have arisen, but prompt action can still save the appearance and function of the fingers or hand. There are others which are faultily treated and become so extensive that when they come under the care of the reliable physician irreparable destruction has taken place and function and shape may suffer greatly. Contractures or stiffness of the joints may result from these infections so that the grasp, the hand's most important function, is impossible. Besides the acute, subacute and chronic septic infections there are other infections by different microbes, as the syphilitic and tubercular, which have a protracted chronic course. They require special consideration.

Among the local infections of the fingers and hand are some of trivial nature, starting from hangnails and small injuries on the side of the nails, the so-called run-arounds or paronychia, which lead to very superficial abscesses and are easily dealt with.

TREATMENT

The treatment of the infection in the hands of the expert surgeon is standardized

and agreed upon. But the treatment by the general practitioner in his office needs some discussion. First of all, every infection of the fingers should be looked upon as a serious matter, because of its possibilities and complications. The consideration that the infection may disappear without any interference and heal spontaneously should never be accepted too lightly. Most of the septic infections lead to abscess formation. It is, therefore, the object of the physician to watch this abscess formation to stem its tide, and localize it if possible. This can often be done by using the passive hyperemia method of Bier on the infected finger. This consists of shutting off the circulation of the finger by the circular constriction of a rubber band used as a tourniquet. I do not believe that many formations of abscess have been prevented, but fortunately we have seen cases threatened with rapid propagation, which were limited to one or two phalanges, or to a felon, by such a rubber band. Heat and moist dressings are the most advantageous remedies, also hot baths and alcohol applications. Heat brings more blood to the infected area and accelerates the formation of abscess. Whether we apply a hot bath, poultice or electric pad is immaterial. Moist dressing with acetate of lead in the form of so-called Billroth solution, boric acid applications, or the thermic lamps are very beneficial. The crucial part of the treatment is the question whether surgical interference is necessary or not, and herein most of the mistakes are made. Sometimes very aggressive activity in the first place is harmful. It is best to decide first when to incise, second, where to incise, and third, how much to incise. As to the first question, when to incise: Many make the mistake of incising too early and therefore unsuccessfully, because the pus formation has not yet reached the stage of a melting process. Fluctuation, the characteristic sign of abscess in a finger, is difficult to diagnose. The second question, where to incise: There are certain rules about this.

It is best to incise in the direction of the blood vessels, not too close to the tendons or joints, yet into the abscess. The last question, how much to incise: Here the practitioner sins most. If he is of an aggressive nature he is liable to incise too much, but many practitioners are too timid and their incisions reach only the superficial surface, not the abscess, and therefore are useless. The incision, however, is not the only thing the practitioner has to think of. He has to establish a successful drainage, and that is best established in many instances by connecting two incisions through an underground channel which is kept open by silk thread, catgut, or tube or gauze.

An important consideration is the after-treatment of such incisions. Moist warm dressings should be continued, irrigations and local baths, with or without additional antiseptics. These depend upon individual taste more than upon absolute indication and have changed from time to time according to the vogue and, perhaps, mostly because of the advertising by commercial interests.

This treatment of incision of abscess

can be done in rare instances with a local anesthetic, but in most cases the patient because of sleeplessness and pain for days is in an excitable condition and is better off when put to sleep for a few minutes. Local anesthesia by freezing is only applicable for very small incisions. Hypodermic injections are very painful so that a few sniffs of gas are most convenient. The after-treatment of a case of chronic suppuration becomes an office routine, as it is often of long duration or the result of a radical and extensive operation in the hospital and the patient does not require hospital care. The after-treatment of cases of chronic infection, after they have healed, in order to improve the function should not be neglected. The office treatment does not terminate when the suppurative process has stopped, but should be continued in the form of massage, electric pads, local baths, and active and passive motion until the function of the hand is restored to the best efficiency possible. Many fingers and hands have been surgically cured, but have remained stiff and useless because of neglect of the all-important after-treatment.

PRACTICAL POINTS IN THE MANAGEMENT OF GONORRHEA IN WOMEN*

CHARLES A. GORDON, M.D., F.A.C.S.

BROOKLYN, N. Y.

GONORRHEA is so common that it should interest every one of us. Just how common no one knows, but amazing statistics might be quoted. We have all seen figures which show that 80 per cent of our population have at some time or other been infected, and that 90 per cent of these have not been cured. It is the commonest cause of sterility, yet it must cause sterility comparatively infrequently, else, with so many not cured, we should not

have to discuss birth control at all. Perhaps the figures are extravagant, but in all probability they are not. Even hasty consideration of its possibilities should convince us of that. One of the most destructive diseases, it is responsible for more sickness and disability than tuberculosis or any other disease we encounter.

Every day, in its chronic forms at least, it is seen by every physician. To the gynecologist it is omnipresent. So common, that he sees it everywhere and has but to

* Submitted for publication November 18, 1929.

guard against its too ready recognition, or diagnosis by suspicion.

The general practitioner must meet the same situation, for on him depends the initial treatment and the all-important duty of informing the patient of the sequelae due to neglect; he must tell her that the cure is necessarily slow, but not at all impossible, and that vanishing symptoms do not always mean disappearance of the lesions.

Its practical diagnosis must not rest upon positive smears. They are too hard to get. All too often they are negative, even in the acute stage. If the smear is positive, so much the easier, but it is well to remember that negative spreads are almost the rule, and that positive results are obtained only after repeated trials or provocative treatment, and often not even then. Any conception of the disease which does not take this into consideration makes recognition hopeless and treatment futile.

With this in mind, how can we recognize it? How is the practical diagnosis made? Certainly not by the smears, but by careful appraisal of the history, and systematic pelvic examination. I am speaking in general terms of course, but what I have to say applies to the vast majority of cases.

First, the history. If the patient says that she never had a discharge until marriage, that is probably gonorrhea. If it has been very profuse from the start, it is certainly so. If the discharge followed parturition, it may be due to laceration and infection of the cervix but the underlying etiological factor is often gonorrhea anyway. Treatment of the cervix will be signally unsatisfactory if this is overlooked.

The importance of urinary symptoms such as burning, urgency, frequency and tenesmus cannot be overestimated. Careful questioning may be necessary to bring out the fact that at some time since marriage or coitus, these symptoms were present, even for a short time.

The menstrual history is valuable, and almost any change that followed marriage is significant. Marriage means pregnancy

or infection, often both. Sometimes we see a gradually lengthening period, from three or four to six or seven days or more, an increasing menorrhagia. Sometimes the menstrual interval is shortened, and menses recur every three weeks, or twice a month, or some other variation of the cycle. Less often periods are delayed, usually with a lessened menstrual amount, gradually approaching amenorrhea. Almost anything is possible depending upon the site and extent of the pelvic lesion. The important consideration is the association of the menstrual disturbance with marriage.

Pain is not a constant factor, but is usually premenstrual and comenstrual, relieved by the flow itself. With dyspareunia and painful defecation, however, pain occurs so often in other conditions that it is corroborative only, and helpful, but not of great diagnostic importance.

Pelvic examination should be preceded in all cases by careful inspection of the vulva, under good light. A head mirror is valuable. In acute cases the intense inflammation of the vulva and the profuse discharge is so characteristic and significant, that diagnosis has to be made but from the acute recurrences which we see so often. There is nothing else like it.

It is with the subacute or chronic case then, that we are most concerned. Look first at the urinary meatus; it rarely escapes. The mucosal redness, edema and pouting of the acute stage have disappeared, but unmistakable evidence always remains. The orifices of the urethral glands are large and red, and the mucosa has lost its uniformly pale color. The urethra is large, thick and sensitive to the finger which strips it carefully in the search for pus, which is of great importance in the diagnosis. As a rule pus can not be expressed until the index finger, following the course of the urethra around the symphysis, presses upon Skene's glands. Thick creamy pus can be nothing else but gonorrhea. Discharge not frankly purulent, thin, small in amount, and apparently from the urethral glands is highly suspicious,

and more often than not, evidence of gonorrhea too. In children it is particularly important to consider all vulvovaginitis as gonorrheal in origin.

Look at the orifices of Bartholin's glands too. They may be seen as two small red points near the last caruncle; the macula gonorrhoeica is diagnostic. The glands themselves may be palpated in the lower part of the labia majora; when they are felt, they are important aides to diagnosis.

The cervix is often atypical and our impression of it may depend upon the stigmata of gonorrhea which we have already seen in the vulva. Endocervicitis in the nullipara is almost always Neisserian in origin. A red cervix with yellow pinhead spots irregularly distributed about a cervical os which is pouring pus or plugged with thick glairy mucus is very characteristic.

Salpingitis is usually salpingo-sophorometritis. It is difficult to conceive of an isolated inflammation of the tubes, and proper appreciation of the point will give us a better idea of the pathology within the abdomen. Palpation of adnexal masses is, of course, not essential in the diagnosis, for flaming tubes with open ends may not be felt at all. The diagnosis is made upon the history, signs in the external genitalia, menstrual disturbance, and often the physical signs of the associated acute or chronic peritonitis.

Treatment should be faithful, painstaking, continuous, and carried out with great attention to detail. It is not in any sense difficult, nor is special training required. Acute cases rarely need local treatment. The speculum and douche are harmful. Copious bland irrigations of the vulva, posture drainage, gentle laxatives and urinary antiseptics are all that the patient needs. Time will bring with it more or less immunity, and general localization of the infection will take place. In its subacute and chronic stages it must be sought out and attacked in the places where we expect to find it. Intra-abdominal complications can best be avoided by

expectant treatment, but it is well to remember that they often occur two or three months after the vaginal infection, whether local treatment has been carried out or not.

Coitus should of course be prohibited. That goes without saying. It is particularly important, however, to observe this rule when dealing with the chronic cases, where the diagnosis, perhaps tentative at first, has been established to our own satisfaction.

The arrangement of the urethral and cervical glands is such that we cannot expect very encouraging results from antiseptics applied to the surface epithelium of the urethral and cervical canals. Fortunately, however, the urethritis is soon confined to a point just within the meatus. With hairpin retractors, the gland orifices are seen, and injected with 5 or 10 per cent nitrate of silver through a blunt short hypodermic needle. Under local anesthesia, the glands may be slit with a cataract knife, or still better, destroyed by a fine tip actual cautery carefully inserted into the lumen while cold, and then heated cherry red. This may have to be repeatedly done, and often preceded by a dilating cold sound which will relieve the not infrequent stricture, and cause an acute urethritis which rapidly subsides. Injections of organic silver preparations are soothing but not consistently bactericidal. Other aqueous solutions are disappointing, but their efficiency is increased by the addition of small amounts of boroglycerine. Injections of the same into Bartholin's glands with a blunt needle are occasionally successful, but generalized infection necessitates resection of the entire gland.

Vulvovaginitis in adults is not a serious problem, as mature squamous epithelium is very resistant to the gonococcus. In children, this condition is best treated by the method of Norris, who depends upon cleanliness of all the parts, careful drying, and general development of the immature epithelium by the use of weak

solutions of nitrate of silver. Treatment is carried out in Sim's or knee-chest position.

Acute endocervicitis should never be treated. It invariably lapses into the chronic form, and, though difficult to treat then, pelvic complications are not so likely to follow. There is no specific treatment. Organic silver salts are useless. Nitrate of silver in 5 to 20 per cent solution is probably our best agent, but it should be cautiously applied to the cervical canal. Large quantities of kaolin applied to the vaginal vault and held in place by a tight dry tampon will be found helpful. Gellhorn's injections of methylene blue 1 per cent, sterile normal saline are very valuable. Though a short hypodermic needle, 1 c.c. is injected into the cervical tissue at three or four points 0.5 cm. from the cervical canal and parallel to it. Packing the cervical canal and vaginal

vault with narrow strip gauze, saturated with 5 to 10 per cent mercurochrome in 50 per cent alcohol will often give good results. Puncture of cysts and striping the cervix with the nasal tip cautery is the latest cure to find favor. It should be cautiously done and not too often. A volume could be written on the treatment of this most intractable lesion, but enough has been said to indicate that intelligent persistent treatment carried out for a long period of time is essential.

Extirpation of adnexal lesions in young women is indefensible. The organism disappears here, long before it can be eradicated elsewhere. Pitiful end results are common. When we come to realize that pelvic exacerbations are nothing more than re-infections, we will more than ever concentrate our attention upon stamping out the disease in the external genitalia and the cervix.

WEBBED FINGERS*

JOHN HOMER WOOLSEY, M.D.

SAN FRANCISCO, CALIF.

WEBBED fingers is a condition in which two or more digits are united by their lateral aspects. They are as a rule congenital but may be acquired, as subsequent to a burn or other injury which destroys the epithelium of the contiguous surfaces of two digits. Contrary to the experience of some authors, the thin web or *main palmé* has occurred in the authors' experience with equal frequency to the fused fingers or real syndactylism. The following method of corrective treatment has been found most adaptable to webbed fingers, that is with regard to the thickness and narrowness of the web.

The procedure is as follows:

The local area is prepared as for surgery and asepsis is employed throughout. Local

anesthesia with 0.5 to 1 per cent procaine, except in infants when an anesthetic is unnecessary, is obtained. A clamp, sufficiently crushing to kill the clamped tissues, is then put on the center of the web. Any type of clamp, varying from the Shoemaker intestinal anastomatic clamp to the ordinary Halsted "mosquito," serves the purpose most satisfactorily. The clamp is held in place by proper bandaging and the fingers immobilized in splints for a period of eight to fourteen days. The crushed tissue becomes a non-vital, dry membrane by four days. It is, however, unwise to move the clamp too soon or to cut the crushed tissue, for the healing is insufficient to hold the skin edges intact until approximately ten days have elapsed. Certainly this is true in the narrow web

* Submitted for publication December 10, 1929.

FIG. 1. Webbed fingers of boy, aged ten.

FIG. 2. Crushing clamp applied.

FIG. 3. Crushing clamp held in place ready for bandage and splints.

of 3 to 4 mm. thickness and, therefore, in this type immobilization for a total of fourteen days is advised.

This pressure necrosis method is possible since the digital arteries, veins and nerves lie close to the phalanges.

Following the usual teaching, the correction of a web on one side of a finger is completed before the web on the opposite

side attacked. The method would seem equally as applicable to webbed toes although, as yet, it has not been attempted. The method has been used up to the age of ten years, but it is best employed in infancy.

The results have been most satisfactory both from a cosmetic as well as a functional standpoint.

CERVICAL LACERATIONS AND INFECTIONS*

GORDON GIBSON, M.D., F.A.C.S.

BROOKLYN, N. Y.

BEFORE taking up the office treatment of these conditions, let us have a clear idea of the pathological processes to which the cervix is prone and try to evaluate the measures necessary for their correction. The most important are congestion, infection, laceration and malignant change.

It is of the first three that we are concerned as far as the possibility of office treatment having any helpful effect. Many a case of simple chronic passive congestion has been called chronic endocervicitis. The dictum that every lacerated cervix is infected does not stand the test of careful clinical investigation. True, a great many are, and in many cases it is at times extremely difficult to differentiate between infection and congestion and as congestion renders any structure more susceptible to infection, the picture is more complicated.

A careful history and thorough physical examination will often reveal that although there is leucorrheal discharge and the cervix is lacerated, enlarged, everted and eroded, the cervix is more sinned against than sinning, the condition in the cervix being the effect of other lesions as well as of the lacerations. The commonest condition is subinvolution. For many years we have used the term subinvolution of the

uterus, whereas in reality the condition is one of subinvolution of the entire pelvic contents, and the underlying lesion a subinvolution of the uterine supports. If one will carefully determine in such a case the excursion of the uterus, one is often surprised to find that he can push the uterus up into the plane of the brim or down into the introitus; that he may hold it tight against the pubis or push it back into the hollow of the sacrum.

The question naturally arises, where is this uterus when the woman is on her feet? The old examination of a woman in a standing position had much merit and often would reveal conditions unthought of if the examination was carried out in the usual manner. Before such a woman in the child-bearing period is subjected to any operative procedure on the cervix, even though there may be some degree of laceration, she should be treated with the idea of stimulating involution of the uterine supports and of the uterus as a whole.

Again, careful examination will reveal the fact that many of these women are of the ptotic type with poor general muscular tone, faulty posture, flat feet, varicose veins, etc.

Before such a woman's cervix is con-

* From The Department of Obstetrics and Gynecology, Long Island College Hospital. Submitted for publication December 18, 1929.

demned to surgery, much can be accomplished to improve her general condition and to stimulate involution. Tonics, proper

there is infection, examination will often reveal a slight amount of tenderness in the pelvis, generally in the parametrium

food, proper rest, attention to the bowels and bladder, tampons, douches, knee-chest posture, and that most valuable instrument, the pessary, will all have a definite place. If there be much erosion, painting with 20 per cent silver nitrate or brushing with the electric cautery will invariably cause complete healing, and if there be extension laceration with considerable eversion, a very deep linear cauterization with a thin blade will often give astonishing results. All of this, of course, takes time and the condition should be carefully explained to the patient lest she become impatient and fail to cooperate.

CHRONIC ENDOCERVICITIS

As said before, at times it may be exceedingly difficult to differentiate between the cervix which is simply congested and the one which is infected. Where

and uterine sacral ligaments caused by a pelvic lymphangitis analogous to the lymphangitis which accompanies infection elsewhere. The cervix may be enlarged, eroded and infected and bathed with a mucopurulent discharge. In long-standing cases, the cervix is cystic and hard with hyperplasia.

Histologic examination of the cervixes which have been removed will show the marked, round-cell infiltration characteristic of subacute inflammation and also show in the majority of cases that the infection only extends from 1 to 2 cm. up the cervical canal. (Figs. 1 and 2.)

Novak pointed out in a recent paper that in the first stage of endocervicitis there is a hypersecretion of the cylindrical epithelium and an extension outward on the pars vaginalis with production of an erosion. In this stage, the erosion is covered with cylindrical epithelium. The latter

still retains its gland-forming tendency so that many gland invaginations may be formed far out on the pars vaginalis. As the inflammation recedes, the squamous epithelium asserts itself again, pushing back the cylindrical epithelium to the region of the external os.

The treatment is obviously the destruction or removal of this infected cylindrical epithelium. This can be accomplished by three methods: operation, caustics or the cautery. The disadvantage of the operation is well known. All surgeons can recall patients who are sterile, who have had abortions or who have had cervical dystocia following operation in the child-bearing period. With this in mind, we believe that other methods should be faithfully tried before operation is advised.

That these cases can be cured by means of the cautery is born out by numerous articles in the literature reporting large series of cases by many observers. It is not our purpose to discuss any series of cases, but rather to describe the method.

We have found that the best results are obtained by using the nasal cautery loop and blade. The transformer should be a noiseless one which can be obtained from any instrument house. The handle should have a finger switch which gives perfect control of the current. Only enough current should be used to give a bright, cherry-red glow to the blade or loop.

The most important factor in the procedure is the management of the patient. She should be told just exactly what one expects to do, that she will experience a fleeting sense of heat and that as soon as she feels it, she is to say so and the current will be turned off. She should be told that this treatment cannot be carried out in one sitting, but that several will be necessary. The necessity for patience and cooperation must be explained.

The cervix is then exposed, any discharge removed and the cold blade laid on the area in the periphery of the erosion one wishes to cauterize first. The current is then turned on and as soon as the patient

feels it the current is turned off. She is then asked, "How much did that really hurt?" and she will generally reply, "Why, not much." "Could you stand another application like that now, or would you rather wait until the next treatment?" Most women will stand from three to six applications the first visit. Others who are high strung and nervous had better be given only one so that their confidence can be obtained. The patient is told that she will have an increased discharge for a few days and that there may be a little bleeding which is unimportant; that she should take a daily alkaline douche and return in one week.

At the next visit it will be found that there is a slough at the site of the cauterization. This may be wiped off and the raw surface touched with an applicator dipped in 10 per cent silver nitrate solution. At this time, several other areas may be cauterized, depending on the tolerance of the patient. After two or three treatments, it will be found that all exposed cervical mucosa and erosion have been destroyed and that squamous epithelium of the portio is covering the area. When this has been done, the lower part of the canal may be cauterized. This should be done with the greatest care for if the cauterization is too deep, distressing stenosis or atresia may occur. Generally four applications at one sitting will be all that is necessary. Douches are continued and the patient returns once a week for cleansing of the slough and stimulation of the squamous epithelium with weak silver nitrate solution. In from two to three weeks following the last cauterization, the cervix will be healed. The time varies, however, a great deal depending on the severity of the lesion and the ability of the patient to tolerate the treatment.

If cysts are present near the surface, they may be punctured with the cautery loop. When there is much eversion, a few deeper linear cauterizations may be made, care being taken not to invade the canal lest one cause stenosis or atresia.

LACERATIONS OF THE CERVIX

We are perhaps too prone to think of lacerations of the cervix as just lacerations, forgetting that the trouble does not lie in the laceration *per se*, but in the changes which may take place because of the laceration. Many a woman has a lacerated cervix, at times quite extensive, who complains of no symptoms and it is only when some subinvolution or infection superimposes that she complains. That a laceration tends to cause sterility is not true. It is only when there is subinvolution with marked passive congestion and increased hypersecretion or infection with again hypersecretion, the latter of the mucopurulent discharge, that spermatozoa cannot pass. Measures to remove congestion and to stimulate involution with cauterization of the infected mucosa in infected cases will be all that is necessary.

The only lacerations which require operation in the child-bearing period are the very extensive ones and here trachelorraphy should be the operation of choice.

When the lips of the lacerated cervix are everted with exposure of the cylindrical epithelium, removal of this exposed epithelium and its replacement by squamous epithelium leaves simply a misshapen portia with a shortened canal lined by healthy cylindrical epithelium. Such a cervix does not predispose to sterility nor will it cause dystocia as there is no scar tissue in the body of the cervix.

Emmett, many years ago, pointed out the danger of scar tissue and so was careful to remove it, and did his careful trachelorraphy hoping for and obtaining primary union without scar tissue formation.

While this paper was being prepared, I saw a young gynecologist do a tracheloplasty on a perfectly good inoffensive cervix with a very mild degree of infection with moderate erosion; one in which a very short period of cautery treatment properly carried out would have been all that was necessary.

So perhaps after all the topic is not untimely.

DEFECTS OF THE TOE NAILS

(INGROWN AND VERTICAL)*

ALFRED AMOS THURLOW, M.D.

SANTA ROSA, CALIF.

THE literature on this subject seems rather meager when we consider the frequency with which we see both ingrown toe nails and the vertical nails.

"Ingrown" toe nails is a misnomer, since the nail is really *overgrown* by the soft parts. Failure to trim the toe nails squarely across the end, which would allow the distal corners of the nails to over-ride the soft parts, is responsible for much of this condition. Narrow toed shoes, low hard toe caps, socks too long or too

short, are also blamed in most articles on the subject. The nail, however, is only a passive offender, and when properly trimmed straight across, leaving the corners square, and not too short, it is practically impossible for the condition to occur.

Vertical toe nails are usually a result of incorrect fit of shoes (too short), in which the crowding of the soft parts of the toe into the end of the shoe results in pushing up the flexible nail. The matrix becomes hypertrophied, and a thicker nail is formed.

* Submitted for publication December 7, 1929.

In cases of ingrown toe nails of long standing, exudate forms in the nail sulcus as a result of the combination of infection

corner of the nail, or a thin strip of gutta percha, often act as a traumatizing factor if worn for any length of time, but do give

FIG. 1.

and trauma, with the inevitable tendency to form tender granulation tissue. By the time the average case reaches the office, the surrounding soft parts are thickened

FIG. 2.

and infiltrated, and palliative measures are a waste of time. Salves have usually been tried before the doctor sees the case, and in the past few years the patient has often secured temporary relief from epsom salts soakings.

Palliative measures, such as gauze soaked in celluloid solution, laid under the

FIG. 3.

temporary relief. Micker of Berlin uses the former method, repeating the process after a few days.

OPERATIVE TREATMENT

The main object being to secure permanent relief by preventing recurrence, operation is aimed at the section of matrix from which ingrown section of nail is formed. If this matrix is not destroyed, nothing permanent has been accomplished.

If the case presents badly infected toes, a dehydration of the tissues by soaking in a strong solution of magnesium sulphate greatly lessens the angry appearance, and shortens the healing time. For two or three days before operation, the patient is asked to carry out this soaking for twenty to thirty minutes twice daily. He is also asked to bring a soft slipper to wear home after the operation.

After iodine and alcohol preparation of the skin of the entire toe, a rubber band ligature is placed around the base of the toe to secure hemostasis. The operative field is surrounded with sterile towels, and with a 2 c.c. Luer syringe a solution of

1 per cent novocaine, with or without adrenalin, is injected into the dorsal surface proximal to the matrix, pushing the needle forward and injecting up to the base of the nail (Fig. 1), then around toward the plantar surface on the side to be operated on, and lastly proceeding distally to the end of the toe, injecting deeply in the last part. If both the edges of the nail require removal, a similar injection is made on the opposite side.

The technic of Von Bergman of the Roosevelt Hospital has been found very satisfactory. Within two or three minutes after the injection of the local anesthetic, incision is made on the dorsal surface, beginning at the cutaneous junction 1 cm. inside of the mesial border, and extending 1 cm. backward so as to expose the whole depth of the matrix at this point when the flaps are retracted. (Fig. 2.) The incision is then carried forward along the mesial side of the nail to the distal end. The flap is so dissected that the entire nail edge and corresponding matrix is exposed, leaving the epithelium of the nail sulcus to be removed with the nail margin. The lateral margin of the nail is now excised, together with its matrix and nail sulcus, and with a small sharp curette all particles of the matrix and epithelium and scar tissue are removed.

The flap is now replaced (Fig. 3) and most operators do not use stitches, but press the flap down firmly and gently bandage over a vaselined gauze compress dressing. In cases where there is but little inflammation, one stitch placed where the incision was begun at the nail border

seems to facilitate union, and does not interfere with drainage.

The soft slipper is worn for a week, dressings being changed daily for the first three days, then every second or third day until healing is complete. It is always necessary to soak off the first dressing but not subsequent ones. The patient should not use the foot for three days.

After ten days an ordinary shoe may be worn, provided the patient has remained off the foot for the first few days. Rapidity of healing is in direct proportion to the length of time the patient remains off the foot after the operation.

The above procedure is practically that of von Bergman at Roosevelt Hospital; the "one-slice" operation of cutting, which the writer has seen others do, leaves much scar and thereon much tenderness with slower healing.

G. E. Ney's method pays no attention to the nail, removing soft parts only, saving skin flaps to cover the area from which the tissues external to the nail have been removed. It may be successful if it is followed by correct trimming and correct footwear.

RATIONAL USES OF PHYSICAL ENERGIES IN OTO-RHINO-LARYNGOLOGY*

A. R. HOLLENDER, M.D.

CHICAGO, ILL.

EFFORTS to rationalize the uses of light, heat, and electricity in oto-rhino-laryngology have occupied workers for more than a decade. The administration of thousands of treatments with physical agents in affections of the ear, nose and throat has resulted in the accumulation of a vast amount of clinical evidence, an analysis of which has enabled the writer to present this resumé of the subject. It is admitted that often the work was carried on strictly for experimental purposes, with no more sound indication than pure empiricism. At other times, the enthusiasm of successes in small series of cases warranted thorough and painstaking trials over a space of time. And still during some periods, the suggestions and experiences of foreign and American investigators in the field seemed to offer sufficient inducement to carry on clinical researches, even though personal endeavors had previously been convincing of either failures or results inferior to those obtainable with customary procedures. These are reasons sufficient to justify the efforts expended, for in no other way would it be possible now to arrive at some definite conclusions concerning the status of physical therapeutics in the specialty. Unfortunately, the amount of laboratory experimentation has been limited. However, as has been stated, an overwhelming collection of clinical data is available, and this must serve as the criterion until more basic studies are made.

RADIANT HEAT LIGHT AND INFRA-RED THERAPY

The utilization of infra-red and luminous rays in oto-rhino-laryngology has served primarily in the acute infections. The infra-red is characterized by

long wave lengths, the luminous rays by shorter wave lengths. The former extends from 64,000 to 6500 Angstrom units; the latter from 8000 Å. units in the red to 3900 Å. units in the violet. The principal local effect of infra-red radiation is the production of hyperemia. Luminous rays have relative photochemical properties, while the immediate action is that of hyperemia and stimulation of lymphatic circulation. All wave lengths of radiation appear to possess some heat properties and the ability to influence chemical reactions. The sources of such radiation are used for palliation of pain or for retardation of inflammatory processes.

That heat may relieve pain is an accepted fact. It acts by diverting blood from congested parts through the production of a collateral hyperemia or the relief of vascular stasis. Heat may lessen nerve sensibility, the result of inhibition acting through the temperature nerves of the skin. The production of hyperemia by the application of heat to a part raises the local tissue resistance by (1) an increased local nutrition, (2) an increased metabolism, and (3) an increased number of phagocytes in the tissues.

Acute Otitis Media. In acute otitis media two immediate factors are definitely called for: (1) relief of pain, (2) drainage. Heat has long been used in this disease for its analgesic properties. Either the infra-red or the radiant heat lamp is superior to any of the older heating sources. The radiation is more uniform and more easily controlled. Its action is decidedly more pronounced. Heat radiation, from any source, is not, however, a substitute for paracentesis of the drum membrane, if this procedure is definitely indicated. Its value is in no way lessened after

* Submitted for publication August 1, 1929.

paracentesis has been performed, for here again heat is the measure of choice, and the facility and satisfaction of applying either the infra-red generator or the radiant heat lamp are well recognized on the basis of clinical experience. Drainage is more quickly promoted and continued and the progress of inflammation retarded. Factors in the treatment which influence results are: (a) good apparatus, (b) long applications at regular intervals, (c) regulation of apparatus and adjustment of distance from ear, permitting radiations of thirty minutes without intolerant effects or untoward reaction of skin surface.

Acute Nasal Sinusitis; Acute Coryza. After the usual treatment providing increased ventilation and drainage, the application of radiant energy has acted as a valuable aid. The principle underlying the application of heat in acute sinusitis is well established. The suggestion here is simply that of an improved source, either the infra-red generator or the radiant heat lamp.

There are practically no contraindications for the application of either the luminous rays or infra-red in acute disease. It is extremely important, however, that their continued applications be not depended upon to do what surgery or other measures usually accomplish promptly. They are not substitutes for other methods of treatment, but, as has already been emphasized, the sources of the energy are improved means of heat generation by which such physical force can be applied in a simple manner and with maximum effects.

ULTRAVIOLET LIGHT

The spectrum of sunlight is limited on one end by infra-red and on the other by ultraviolet rays. The ultraviolet rays are obtainable from the sun, and to some extent by reflection from other natural sources. Artificially for therapeutic purposes, this energy is obtainable from carbon or impregnated carbon arc lamps and from quartz mercury vapor burners.

The data upon which conclusions are drawn in this report is based altogether on mercury vapor quartz lamps, the water-cooled for localizing action and the air-cooled for systemic effect. Ultraviolet rays penetrate tissue much less than 1 mm. The ratio of penetration between skin and mucous membrane is not definitely known, but a comparison of tolerance between mucous membranes of different organs has been worked out roughly by clinical observation. Thus the tolerance of the mucous membrane of the pharynx is small as compared with the tolerance of the mucous membranes of the nose, the ratio being about 1:10 in the average patient. Certain factors influence the tolerance of ultraviolet irradiation of mucous membranes, the chief ones probably being the vitality of the tissue, the presence of excessive moisture and unusual amounts of mucous or other secretions.

As compared with the wave lengths of the other rays already described, ultraviolet ranges from 4100 to 1860 Å. units. Ultraviolet radiation such as is normally present in sunlight tends to stimulate the endogenous growth of cells, accelerates the life cycle and therefore hastens death, whereas the longer wave lengths of light are necessarily of exogenous development and the continuation of growth and repair of waste in the cell.

Ultraviolet radiation has a bactericidal action, which is, however, very superficial. Intense radiation has a destructive action on tissue cells. Ultraviolet light produces certain changes in the blood. The speed of reaction is influenced, both the oxidation of chemical compounds in the presence of oxygen and their reduction in the absence of oxygen. Respiration is influenced, breathing becomes slower and deeper. Other changes have also been noted, further work being necessary to act as confirmation.

Pharynx and Oral Cavities. Opportunities to treat tuberculosis and lupus of the pharynx and oral cavities are not so great in clinic and private practice. The few cases which have been attended responded favor-

ably. As Cemach has remarked, "Owing to their easy accessibility, oral and pharyngeal mucous membranes have been proved to be the most satisfactory objects for local light therapy." Cemach's series consisted of 13 cases thus treated, tuberculosis of the pharynx 3, of the cheek 3, of the tongue 2, of the gums 1, and further 4 cases of lupus. Twelve cases were cured completely, while one was only improved. Cemach also quotes Wessely who treated 35 cases with 28 recoveries, and Schreyer who treated 15 cases of lupus with 14 recoveries. Spitzer (Lupus Institute, Vienna) has treated 6 cases of acute tuberculosis of the oral membrane with good effects.

In disease of the tonsils little or no curative action is obtained with localized ultraviolet irradiation. This, in spite of the fact that many enthusiasts claim all sorts of favorable reactions. In isolated cases, occasionally, some good results were obtained, but the difficult problem of controlling these results renders them questionable. Likewise, the uniformly good results of some in treating Vincent's angina with quartz light have not been duplicated by the writer.

The Nose. Skin conditions of the external nose sometimes respond favorably. This has special reference to the eczematous eruptions. Acne rosacea is rarely affected. Tuberculosis and lupus of the nasal membranes, unless easily approached, do not react well to ultraviolet, although frequently this agent serves as good adjunct treatment. So far as other localized intranasal diseases are concerned, ultraviolet irradiation cannot be said to produce uniform results of any kind. Now and then a favorable action is secured. In general it may be said that ultraviolet light produces a bactericidal action on that part of the mucous membrane which the radiation reaches, this action for certain organisms varying with the radiation time. There is nothing accomplished in nasal accessory sinus disease by intranasal irradiation of quartz light.

The Ear. Skin affections, especially

lupus, react well to ultraviolet irradiations and good results are the rule. Certain types of middle-ear suppurations frequently improve, and in some, suppuration ceases when treated with quartz light. No definite indications can be made and the only test is the therapeutic one. Cemach states that middle-ear tuberculosis reacts to all forms of ultraviolet light. He also recommends the resorbing effect of the quartz light as postoperative treatment of septic ear cases. This appears to be a logical and reasonable indication.

The Larynx. What has been said regarding the treatment of tuberculous conditions of the pharynx and oral cavities applies here. Few cases remain under treatment at the clinic, practically all of them sooner or later being referred for sanatorium care. No definite statements can therefore be made from personal observation. The largest number of cases reported upon in the literature is by Strandberg of the Finsen Medical Light Institute. A late communication embraces 203 cases, mostly of moderately severe and severe tuberculosis of the larynx. The majority of these were ambulatory cases of which number 55.6 per cent were clinically cured. Strandberg's methods include the use chiefly of general irradiation with carbon light baths without local irradiation of the center of the disease. The quartz light is employed on exceptional occasions.

THE GALVANIC CURRENT

This current may be derived from a wet cell, a dry cell or batteries, or from the lighting mains through a motor generator set. When the current from the mains is alternating in type a motor transformer or electrolytic rectifier is necessary to change it over to a direct current.

Galvanism is employed either for its polar effects or for the ionization of certain drugs or metals. Such terms as cataphoresis, anaphoresis, iontophoresis, ionic medication are more or less synonymous and vary only in technical detail. The action of the galvanic current is

primarily a chemical one. The contrasting reactions between the acid positive pole and the alkaline negative pole are proved by simple laboratory test. When applied to tissue the positive pole acts as a vasoconstrictor, the negative as a vasodilator. The action on metals of the two poles is sometimes of interest. The positive pole oxidizes and corrodes metals. The negative pole has no power of oxidation. It is said that the positive pole has distinct sedative properties in contradistinction to the irritant action of the negative pole. This sedative effect of the positive pole cannot, however, always be demonstrated clinically.

Ionization is defined as that treatment which consists in the introduction into the tissues of minute particles called ions by means of the electric current. Bases, metals and alkaloids are electropositive and therefore should be placed on the positive pole. Acids and acid radicals are electronegative and should be placed on the negative pole.

In otolaryngology, medical ionization has been used to advantage for two very definite indications, chronic suppurative otitis media, and chronic intumescent or moderately advanced hypertrophic rhinitis. It should be emphasized, however, that only selected cases of either of these conditions respond favorably to ionization.

Chronic Suppurative Otitis Media. The technic of zinc ionization as suggested by Friel is the only one which has been used. In selecting cases for this method an attempt has been made to follow the rules laid down by this worker. "Tympanic sepsis, meaning by this, infection of the discharge rather than infection of the living tissues, is clearly a case for antiseptic treatment such as zinc ionization." The perforation in the drum should be large enough to permit the zinc solution to enter the middle ear, or if this is not the case, a small cannula should be employed to introduce the fluid. Occasionally the ischemic action of adrenalin, or a combination of cocaine and adrenalin

solutions, serves to give better access to the perforation. Only simple uncomplicated chronic otorrhea is an indication for zinc ionization with anticipation of a curative result. Other types of middle-ear suppurations sometimes react favorably by way of improvement for longer or shorter periods of time, but the experience of many clinicians has shown that in the presence of any complicating pathology permanent cessation of the aural discharge does not occur. Friel advocates zinc ionization for indications other than mentioned, but the writer has limited himself both in his clinic and in private practice to this very definite indication.

Nasal Zinc Ionization. For intumescent rhinitis, and for mild forms of hypertrophic rhinitis, zinc ionization has been found to give more satisfactory results than many of the older non-surgical methods of treatment. The cases must be carefully selected, for there is no unanimity of opinion concerning the nasal structures involved. Likewise there is a difference of opinion on the part of some authors regarding the strict meaning of "intumescent" and "hypertrophic." In the early stages of simple chronic rhinitis, there are the usual inflammatory changes in the mucous membranes, but the thickening varies according to the duration and severity of the nasal involvement. The term "intumescence" implies a swelling, but not necessarily one of permanence. As Phillips puts it, "In the hypertrophic or hyperplastic form, chronic rhinitis is an inflammatory process which involves the nasal mucosa, more especially the turbinal tissues and is accompanied by permanent increase in the soft tissues and changes in the character of the secretions." Markedly advanced rhinitis with fixed connective tissue or polypoid changes should be excluded as an indication for zinc ionization. The method of treatment of zinc ionization is simple and can be carried out in very young children as well as in adults. In older children, in particular, it is of merit because it sometimes relieves the

nasal symptoms of obstruction until such a time in adult life when surgery can be instituted if so desired. Long strips of narrow gauze packing saturated with a weak solution of zinc sulphate (0.5 per cent) are packed into the nasal chamber to be ionized. Every surface of mucosa should be covered down to and below the inferior turbinal. The moistened gauze is a conductor of electricity and when the current is turned on, only those parts will be ionized adequately which have been brought into the circuit by good contact. The positive pole of a galvanic current is connected with the wet nasal packing, the negative pole to a large wet pad on the forearm or other surface. As has been frequently stated, the current must be controlled from the lighting mains by a generator set. In fact, this is the most desirable plan at present, because the set has a milliamperemeter, polarity changers, indicators and such other refinements as make for perfected technic. Up to 10 ma. may be employed for from ten to fifteen minutes. The maximum effect should be reached after ten minutes. As a general rule only one ionization is necessary, but occasionally a second or a third treatment makes the result of relatively longer duration. There is no reaction which causes any discomfort to the patient. Definite changes in the appearance of the surface of the mucous membrane occur. These are referable to color and presence of secretions, both of which are altered immediately, due to the surface action of the zinc and the pressure of the packing. The electrolytic effect is undoubtedly also a surface one, but must be studied microscopically to be described accurately.

F.H.B. Norrie advised the use of zinc electrolysis for enlarged inferior turbinates, as an alternative to the cautery or turbinectomy. Its chief advantages are absence or minimum reaction and no destruction of nasal tissue. Norrie uses preliminary cocaineization. The needle is inserted into the turbinal and pushed along it under the mucous membrane and close to the bone for whatever distance is considered neces-

sary, care being taken that the needle does not puncture the mucous membrane again further back. The current is increased up to 10 ma. and continued for ten minutes, after which it is slowly reduced and reversed for a few minutes so as to allow easy withdrawal of the needle. A pure zinc needle, properly insulated, is essential for the avoidance of burns of the mucous membranes.

DIATHERMY

To the best of our present knowledge, diathermy is a form of thermotherapy which utilizes electrical energy for the production of thermal effects in the depths of the tissue. The rise of temperature is said to be proportional to the amount of resistance encountered by the current. Medical diathermy is differentiated from surgical diathermy by the destructive action of the latter which is produced by carrying the heating effect beyond physiological limits. Whether heat is the one and only physiologic action of diathermy is at present a mooted question. If other effects are produced they have not as yet been conclusively demonstrated either by laboratory or clinical tests.

The chief indications for diathermy are deep seated affections. In such it may be employed independently or combined with other agencies such as galvanism, sinusoidalism or the x-ray.

A diathermic current has no polarity, and therefore reference to polar action or usage is erroneous. It is said that heat is generated in the tissues in proportion to the square of the amperage employed and the resistance of the tissues to the passage of the current. It has been stated also that the high frequency current because of its high voltage, is probably able to take a direct path through the tissues and is not influenced materially by their relative resistance. This latter contention has not been conclusively proved and is therefore open to argument.

Briefly the physiologic effects of medical diathermy may be classified as local and

general. Logically the resultant action of diathermic application include (1) mild skin hyperemia, (2) sedation, (3) improved blood and lymph circulation. Factors which will alter the degree of either of these actions are duration of treatment, size of electrodes and frequency of administration. When uniterminal diathermy is used, because of the higher frequency and higher voltage, the heat produced is more superficial and cannot be localized or directed into deeper tissues. The body acts as a condenser to these currents which are easily diffused and dispersed and not easily controlled. The local effects of surgical diathermy depend on the intensity of tissue destruction desired, and this depends on the utilization of electrocoagulation, electrodesiccation, or fulguration. When either of these is employed, marked reaction of the tissues takes place. Edema and sloughs are of common occurrence.

The general effects of diathermy, aside from the slight elevation of body temperature, are more or less conjectures. It is true that a lowering of systolic blood pressure has been noted, but this lowering is usually not of a permanent nature except in isolated cases. In otolaryngology the local effects of diathermy are of chief importance. Therefore, further consideration of the general action will not be discussed.

Nasal Accessory Sinus Disease. Before applying medical diathermy to a diseased nasal accessory sinus, the case must be carefully selected for this treatment. Clinical diagnosis should be supported by roentgenographic evidence so far as this is possible. Diathermy is not indicated in the presence of pus in a sinus cavity unless adequate drainage has been provided, nor is diathermy indicated in any instances in which surgery has been established as the rational therapy. An example of this is polyposis or polypoid degeneration of the mucous lining. There are numerous instances, however, of sinus disease without surface suppuration of the mucosa,

which give symptoms of pain or discomfort, and tenderness. Irrigations often prove valueless. Surgery might prove beneficial, yet conservative measures merit a trial first. It is for such an indication that diathermy has proved beneficial.

The frontal and maxillary sinuses are easily accessible and lend themselves to direct diathermy. Heat within the tissues of the sinus cavity is effected by this method. It is analgesic in acute, subacute and chronic involvement, lessens symptoms by its ability to produce a local active hyperemia and improves the blood and lymph circulation to the part. Thus tissue drainage is promoted.

Experience has demonstrated that whereas the frontal and maxillary sinuses respond favorably to diathermy when heat is an indicated factor in the treatment, inaccessibility of the sphenoid and ethmoid sinuses has caused difficulty in the technical application of the direct method. The results in sphenoid and ethmoid disease have not been satisfactory, and until scientific means of administering the energy are devised, negative results may be anticipated.

The value of diathermy as an aid in the postoperative treatment of sinuses has recently been suggested. This is especially noteworthy when healing is delayed for some reason, such as devitalization of the part. On the whole, diathermy cannot be said to replace any of the usual procedures, medical or surgical. It is, however, an added means at our command for conservative therapy and should be thoroughly tried, particularly when other methods have been ineffective. Results will depend on correct technic, good apparatus and individualization of treatments, based on the existing symptoms and pathology.

Chronic Middle Ear Deafness. An analysis of over 300 records of patients with middle-ear deafness selected for diathermic treatment shows that improvement was obtained in 50 per cent of the cases. In each instance the diagnosis was made by

the usual tuning-fork tests and by the whispered and conversational voice tests. The audiometer was used as a final aid and also in checking progress of patients under treatment.

The method of diathermic application consisted of placing the smaller or active electrode over the mastoid region of the affected ear and the larger or indifferent electrode on the opposite side of the face, approximately over the area of the malar bone. Three to six treatments were given weekly, each treatment being of twenty minutes' duration.

Diathermy has benefited some patients with middle ear deafness after other methods had failed. In the experimental studies conducted during the past six years, cases were always carefully selected on a treatment basis and controls employed to evaluate each form of therapy, singly or in combination. Routine measures are never contraindicated. On the contrary, they sometimes are more effective with the adjuvant use of diathermic therapy.

Physical agents have failed to yield favorable results in advanced middle ear deafness, and in otosclerosis and nerve deafness. In fact, exaggeration of symptoms has been frequently noted when these types of impaired hearing have been under the influence of diathermic administration.

There is still much to be accomplished in the treatment of partial deafness with physical methods. General utilization by otologists of diathermy and other physical agents is warranted, not only on the basis of the experimental work already done, but in the hope that further progress will result.

OTHER USES OF MEDICAL DIATHERMY

Medical diathermy has been used experimentally and empirically for a number of affections in otolaryngology. There is yet to be established a definite rationale for indications other than those already discussed. There is little doubt concerning the value of uniterminal diathermy for

certain endonasal indications, but until further evidence is presented to augment what proof is now available, its employment must be regarded simply as an empiric form of therapy. Diathermy is now being utilized in chronic non-specific laryngitis and tracheitis. Further work is necessary to demonstrate its merit for these affections.

SURGICAL DIATHERMY

As a local agent for the destruction of new benign or malignant growths, surgical diathermy represents one of the true advancements of modern surgery. Its usefulness lies chiefly in its ability to destroy accessible growths with a minimum of hemorrhage and without danger of dispersing cancerous cells. Various technics for electrocoagulation have been suggested. The cutting current is now extensively employed for mass extirpation. No one method has proved ideal. Individualization is essential and the surgeon who adopts a certain technic on the basis of surgical indications will obtain the best results.

Surgical diathermy is the agent of choice for malignant growths of the antrum, the tongue, the lips or the larynx. Complete and permanent eradication of accessible neoplasms of the ears, nose, or other easily approachable parts of the head and face will depend on the type of growth encountered. Biopsy is important and histologic study of the removed tissue is always necessary to determine the value of follow-up treatment.

Carcinoma of the larynx can be approached in two ways: by suspension preceded by tracheotomy, or by laryngofissure. Obviously the choice of approach will depend on the extent of the growth and the condition of the patient. The permanency of results can only be predicted by the absence or presence of metastases. The difficulty has always been in getting patients early enough, before the glands have become involved, for the prognosis

is in direct relationship to the localization of the growth.

The problem of anesthesia in connection with surgical diathermy has always been seriously considered. Much work has been done with rectal and spinal anesthesia. Certain new drugs have been tried. The matter is still unsettled, but with the experimentation now being indulged in some good should result.

SUMMARY AND CONCLUSIONS

1. While physical therapeutics in otorhino-laryngology is still more or less experimental, a vast amount of clinical evidence is available to prove the usefulness and rationale of certain physical energies in selected cases which come in the scope of the specialty.

2. Radiant heat-light and infra-red are serviceable in acute otitis media, preoperatively and postoperatively, and in acute upper respiratory infections.

3. Ultraviolet energy has proved beneficial for tuberculosis and lupus of the

pharynx, larynx and oral cavities and for some skin affections of the nose and ear.

4. Zinc ionization for selected cases of chronic suppurative otitis media and for intumescent and moderately advanced hypertrophic rhinitis represents a definite advance in the therapy of these diseases.

5. Medical diathermy is of value in acute and chronic forms of frontal and maxillary sinusitis, but must be employed with due regard for underlying factors, principally that of drainage when suppuration is present.

6. Middle-ear deafness is an indication for medical diathermy, especially after the usual methods have failed to bring about improvement. Recent reports by Hilliard and McKenzie appear to confirm the results reported upon earlier by some foreign and American otologists.

7. Surgical diathermy is unquestionably the agent *par excellence* for the destruction of accessible new growths, whether benign or malignant, providing, however, there is absence of metastatic involvement.

THE SEDIMENTATION TEST

A SUBSTITUTE FOR THE LEUCOCYTE COUNT*

DONALD TOLLEFSON, M.D.

LOS ANGELES, CALIF.

NUMEROUS articles have appeared in the literature from time to time on the erythrocyte sedimentation test. Friedlander in this country was among the first to advocate its use. Baer and Reis, Polak and Mazzola, Schmitz and Schmitz, and others, have reported their experiences. Opinion is almost uniform that taken in conjunction with the physical findings, the sedimentation test is of definite value to determine the presence or absence of infection.

The rate of settling of the red blood cells from a citrated column of serum,

when allowed to stand, is known as the sedimentation time. While its use has been more or less confined to hospitals, and especially to gynecological departments, the simplicity of technic makes it both practical and valuable for office practice.

TECHNIC

Draw 0.2 c.c. of a 5 per cent sodium citrate solution into a 1 c.c. graduated tuberculin syringe. With a small hypodermic needle attached, draw 0.8 c.c. of blood from one of the small veins in the

* Submitted for publication November 19, 1929.

arm; thus making 1 c.c. of a solution of citrate blood, which is placed in a standard calibrated tube. Shake thoroughly by in-

| | Minutes |
|----------------------------|---------|
| Normal pregnancy..... | 110 |
| Postpartum afebrile..... | 52 |
| Abortions, 2 to 3 mos..... | 68 |

FIG. 1.

verting the tube, and take the time. When the erythrocytes have settled to the 18 mm. mark, leaving the clear serum above, take the time again. The difference in minutes is the sedimentation time.

The normal rate for the average healthy individual is about 120 minutes. The following readings show some of the common infections and their locations:

| | Minutes |
|------------------------------------|---------|
| Infected abortions..... | 30 |
| Pelvic abscess..... | 16 |
| Breast abscess..... | 23 |
| Active salpingo-oophoritis..... | 38 |
| Parametritis recent..... | 36 |
| Fibroids and pelvic infection..... | 65 |

When the rate is below thirty minutes, localized accumulation of pus either in definite abscess formation or in minute foci will be a constant finding.

Certain conditions named below show rapid readings not accounted for by infection:

Here some absorptive phenomena must account for the rapid settling of the cells.

In malignancy, the rapid readings are due to a secondary infection of the malignant growth.

Following operation the rate drops thirty or forty minutes, but within a week's time it is again nearly normal. The absorption from tissue destruction may account for this change.

In secondary anemia the rate is not materially altered; when it is, a careful search for foci of infection will usually explain the change.

In elective operations, one is certain to meet with cases where although physical findings and the temperature are normal, infection is suspected. It is in this type of case that the test is of most value. Whenever the rate is below ninety minutes, operation should be postponed until the

rate is normal or sufficient time has elapsed under conservative treatment to make it apparent that operative interference is essential for recovery.

In fibroids associated with pelvic infection, the rate in 37 cases examined at the Long Island College Hospital in Brooklyn was sixty-five minutes. In every case foci were found to substantiate this determination. In most cases under expectant treatment the rate would approach normal in a few weeks, and operation was then performed. When cases were operated upon with a sedimentation time of less than ninety minutes, the postoperative course was attended with more complications, and the convalescence prolonged. The end-result of the operative procedure was also less satisfactory.

In the diagnosis of ectopic pregnancy of recent origin or rupture, the sedimentation rate will be normal. In 25 such cases the average rate was 108 minutes, compared with 32 of acute salpingitis, showing an average rate of thirty-six minutes. In both conditions the physical findings, leucocyte count, and temperature may be entirely similar. A slow rate, or one approaching the normal, will suggest ectopic pregnancy, while a rapid rate will indicate that an active infection exists. In old ectopic cases, rapid readings are due to infection of the blood clot in the peritoneal cavity.

A tubal insufflation test should never

be done in the presence of infection. A sedimentation rate will diagnose infection, if present.

If a test aids our diagnostic methods, it will be added to routine laboratory analyses in hospitals; but, if it is the least bit difficult it cannot be used in office practice. The leucocyte count is not done in most physician's offices unless he is equipped with a laboratory technician. The solution and pipettes require considerable care. A microscope is also necessary. The information obtained by leucocyte count is no greater than that determined by sedimentation. In addition the sedimentation rate is much more simple, requires no elaborate technic, and may be done by anyone in his office capable of doing a venous puncture.

CONCLUSIONS

1. A rapid rate means infection, a slow settling of the red blood cells eliminates this possibility.
2. It can replace the leucocyte count because it gives as much information and is not subjected to so many changeable factors.
3. The diagnosis of latent or quiescent infection is a valuable adjunct to elective surgery.
4. It will be found to be of value in diagnosis of ectopic pregnancy.
5. It is simple to perform and therefore may be used in office practice.

REMOVAL OF FOREIGN BODIES FROM HANDS, FINGERS AND FEET*

DAVID GOLDBLATT, M.D.

NEW YORK

THE frequency of the incidence of foreign bodies in the hands and fingers and the relative ease with which those more superficial can be excised, makes the problem of their removal of inter-

est not only to the surgeon but to the general practitioner as well. That often the search for foreign bodies taxes the patience and skill of the operator would indicate that unless the offending body is superficial

* Submitted for publication December 18, 1929.

and easy of approach, it were best left for removal in the hands of those trained by experience to do this.

Because the relative frequency of foreign bodies in the hands and fingers is much greater than in the feet, and since the principles advocated apply to both, this article will concern itself chiefly with the removal of foreign bodies from the hands and fingers and limit itself to those foreign bodies visible in the x-rays.

Certain general principles applicable to foreign bodies anywhere, and to the hands and fingers particularly, present themselves as a working basis in the management of foreign bodies, as follows:

1. Most foreign bodies are a source of irritation, either immediate or remote, and wherever possible should be removed.

2. Early removal makes for easier removal and prevents slipping and progression of the foreign body along the tissue planes.

3. Where the foreign body is sharp and pointed, as a needle, pin, nail, etc., early splintage of the part maintains the relation of the foreign body to the tissues similar to the time of entrance and makes localization and removal easier.

4. The introduction of a foreign body into the tissues not made with surgical intent produces an infected punctured wound which should be sterilized by the injection of $3\frac{1}{2}$ per cent tr. iodine by means of a hyperdermic needle, if the condition is seen early.

5. Where contamination by street dust is suspected, a prophylactic injection of tetanus antitoxin should be given.

6. Localization of the foreign body should be made before any attempt at removal is initiated as it saves embarrassment and facilitates the operation. For this purpose the use of a skin marker after visualizing the foreign body by means of the fluoroscope and projecting on the skin its approximate localization, is of material aid. X-rays in two planes, anteroposterior and lateral, should be before the operator while working, thus determin-

ing the relation of the offending body to the hard parts and the vital soft structures. The use of the tell-tale marker preliminary to the x-ray is of decided help in some cases. The use of the fluoroscope, where available, is of great value in extracting foreign bodies. Where neither the x-rays, nor the fluoroscope are available, transillumination with a strong light in the dark may give a clue as to the location of the foreign body. Discoloration of the deeper parts by the foreign body in its passage into the tissues may be a clue to finding it.

7. Anesthesia, either local or general, should be used. Where local anesthesia is used, $\frac{1}{2}$ per cent novocaine solution injected at the root of the fingers to block the digital nerves for finger work; or at the wrist to block the median and ulnar nerves for palm work; or infiltrated locally over the foreign body, produces adequate anesthesia for the removal of the ordinary foreign bodies. Where the foreign body is located in the hard parts and requires bony excision, general anesthesia is preferable.

8. Drainage. Assuming that every foreign body not introduced aseptically may produce an infected wound, we prefer to drain every operative wound after the removal of the foreign body. For this purpose we use a sterile rubber-band drain.

9. The use of natural or electro-magnets has, in our experience, proved most ineffectual in the removal of foreign bodies of the hands and fingers.

10. While it is the writer's conviction that the best surgical work can be done only under proper condition, preferably in an operating room, yet where the foreign bodies are in the fingers or superficially situated in the hand, they can be removed at the office.

Surgery of the hand and fingers presents a difficult problem both because of their anatomic structure and function of these parts and because of the susceptibility to, and easy destruction by infection of some of the more important structures

found here. The sloughing of tendons as well as destruction of the phalanges, following hand infections, with subsequent

important anatomic structures here (digital vessels, nerves and tendons), and incises parallel to these. If the offending object

FIG. 1. Foreign body imbedded in head of metatarsal of little toe.

FIG. 2. Skin marker almost overlapping foreign body.

deformity of the fingers are well enough known to be mentioned here only in passing; and it is because of the easy destruction of these structures that any operative procedure undertaken here should be looked upon in the light of a major, rather than a minor surgical problem. The relative functional value of the different fingers should also be considered, and it should be remembered that they are important in the order named: thumb, index, middle, little and ring fingers. Foreign bodies are potential sources of introducing infection and, therefore, are important factors in hand infections.

PROCEDURE OF REMOVAL

Fingers. When a foreign body is situated in the fingers its removal is often an easy matter if one bears in mind the

is elongated and parallel to these structures, the usual incision, bisecting the foreign

FIG. 3. Skin marker projected approximately over foreign body.

body, is made with a knife through the skin only, and further exploration is made with a blunt instrument, as an artery clamp,

until the familiar gritting sensation of metal-to-metal contact is sensed, and the object is grasped and extricated. When possible cutting across the pad-like cushions at the tips of the fingers, as well as the anterior surfaces of the closed spaces, is to be avoided, as scarring here may interfere with the important tactile sensation located over these areas. Where the foreign body is impacted in the bone, it is best approached from the side of the finger, making a generous incision for an adequate exposure.

Hand. In the palm, searching for foreign bodies becomes more difficult, both because they have a deeper range of penetration here, and the anatomic structures are more extensive. The superficial and deep vascular palmar arches and the neural palmar arch as well as the numerous flexor tendons here should be remembered and avoided. Where the foreign body is superficially located, incision with a knife is made through the skin only, bisecting the foreign body and sufficiently large to give a good visual exposure. Blunt dissection with the tip of an artery clamp is then carried out until contact is made, as in the fingers. When the foreign body is deeply located, below the palmar fascia or in the palmar spaces, its removal may be quite difficult. It sometimes becomes necessary to make a more extensive exposure than a linear incision bisecting the foreign body gives, especially where the foreign object is a needle lying at an angle between 45° to 90° to the skin surface and deeply imbedded in the palm of the hand. A flap incision in the skin, either surrounding the foreign body; or one leg of the flap bisecting, or as nearly as possible bisecting it, gives the advantage of increasing the operative field by retracting the flap. A good visual operative field, which really means a sufficiently large operative field, is essential for good work.

The following case is cited to prove that sometimes an apparently innocuous foreign body of long retention may become the irritative factor in a symptom-complex simulating another disease:

J. R. a well-preserved man of sixty years, presented himself in 1926 with the following history and findings:

For the past five years he had been suffering from a symptom-complex consisting in periodic pain, swelling, redness, and disability of the right foot. The pain would come at night more often and was of sufficient severity to require opiates for relief. The weight of the bed-clothing would produce pain so that a cradle was used for that foot. Medical attention here and abroad consisted in symptomatic treatment during the attacks and the general hygienic and medicinal treatment for gout in the intervals between attacks. The attacks would last four to five days and the pain would gradually become less and remain so during the free-from-attack interval which would last about four to six weeks. He presented an x-ray taken abroad about three years before where he was told that the buck-shot lodged in his foot, which he remembered being in there about forty years, had no relation to his condition.

Examination of the blood serologically, chemically and cytologically was negative. The urine and general body physical examination were negative. The right foot showed an atrophic condition of the skin over the dorsum, otherwise the part was negative. Motion in the ankle and the joints of the tarsus and toes was normal. The free-from-attack period had lasted about three weeks at the time of presentation of the patient. An x-ray was ordered, and revealed the buck-shot as in the accompanying illustrations. Removal of the foreign body was advised and done. At operation the buck-shot was found buried in head of the metatarsal of the little toe with an associated periostitis of the metatarsal. Following the operation the patient had been watched and seen periodically for one year and during this time no attack has occurred. The removal of the foreign body stopped what seemed like a gouty symptom-complex.

INDICATIONS FOR DOING A MEATOTOMY & A SIMPLE TECHNIC THAT CAN BE DONE IN THE OFFICE*

GEORGE F. SCHENCK, M.D.

LOS ANGELES, CALIF.

A NARROW meatus occurs in the distal 1 cm. of the urethral canal and is bounded by the external and internal meatus.

A narrow meatus exists in the infant when there is a small orifice that will not admit a No. 10 F. sound, and in the adult when it will not admit a No. 22 F. sound. The condition is the most frequent of any urological condition. It is the commonest cause of urinary obstruction with its serious sequel in infants. It is the most frequent cause of inadequate drainage of the urethra. The latter condition invites specific and promotes many non-specific infections. In cases there is an indication to instrument the urethra or bladder, it is the commonest hindrance. It may be congenital or acquired.

Meatotomy is one of the easiest and simplest of all operations. Yet it is probably the most neglected operation in the realm of surgery. The operation should be done in the office every time a narrow meatus is found to exist before attempting instrumentation of the urethra.

The technic I use is as follows: The end of the penis is washed with soap and water and the field of operation is anesthetized by inserting a cotton applicator soaked in 4 per cent butyn (adrenalin) solution. After this has been in the meatus for ten minutes, a sharp, blunt-pointed bistoury is inserted into the urethra, well within the second meatus, the head of the penis is compressed from side to side tightly, and the knife withdrawn, cutting the floor of

the urethra to a depth that apparently removes the obstruction and eliminates the pocket that exists behind it. The desired result in skillful hands should be achieved with a single stroke. It is important to remember that the internal meatus, at the depth of 1 cm., is often tighter than the meatus itself. A No. 28 F. bougie is introduced immediately. If it will not pass readily, or catches on the constriction as it is withdrawn, further cutting is required.

If adrenalin has been employed, the bleeding is usually slight, but gentle lateral compression should be applied by the operator until it subsides. The patient is instructed how to stop bleeding by lateral compression of the glans penis in case there is a recurrence. It has been my custom to apply half inch bandage bound with narrow strips of adhesive in such a manner that it compresses the edges of the wound, but permits the patient to urinate without removing the bandage. Then, I place a piece of sterile gauze over the end of the penis and fix it with a small rubber band. The latter is easily removed when the patient urinates. The patient is instructed to keep the wound anointed with sterile vaseline, and after three days, to keep the cut edges from healing by pulling them apart twice daily. No attempt should be made to pass a sound before one week has passed.

The results are uniformly good, and I have never seen any complications from a meatotomy other than slight bleeding, that is easily controlled by the patient.

THE TREATMENT OF PARAPHIMOSIS*

GEORGE F. SCHENCK, M.D.

LOS ANGELES, CALIF.

PARAPHIMOSIS usually occurs when a phimosis has been forcibly retracted behind the corona glandis, and remains there to produce a constriction. The inflammatory causes are balanitis, gonorrhea, chancre, chancroid, and herpes. Immediate treatment is indicated to prevent edema, ulceration and gangrene.

1. A simple paraphimosis can invariably be reduced without incision, if the following details, as enumerated by Keyes, are observed, viz:

(1) The stricture must be pulled well back. Exceptionally, the mucous membrane is unfolded at the dorsum; this must be smoothed out by still further retracting the prepuce.

(2) The edema must be thoroughly squeezed from in front of the stricture to the shaft of the penis behind it.

(3) Reduction is then accomplished by forcing the stricture slowly over the head of the penis. It is futile to attempt to pry the stricture over the glans until the edema has been reduced.

A liberal application of vaseline to the glans and prepuce will aid materially in persuading the stricture to slide over the glans. If a patient and skillful attempt at reduction fails, the stricture must be divided. Under local anesthesia, two longitudinal incisions are made in the depths of the constricting ring, which is above the edematous mass of skin and subcutaneous tissue, through the skin and subcutaneous tissue dividing the stricture until the prepuce can be easily drawn over the glans. The incisions should be about 1 inch long, and had best be closed transversely according to Heinecke's principle. This will

enlarge the preputial orifice, cure the phimosis and prevent future paraphimosis.

2. In case a chancre or chancroid is the exciting inflammatory cause of paraphimosis, a bilateral slit (never a dorsal) should be made to make the source of infection accessible and to prevent the destruction of tissue. The quicker it is done the less obstinate the infection will be. Under local anesthesia, the mucosa should be divided with scissors down to the corona, and then the skin and subcutaneous tissue through and above the constriction until the prepuce is redundant. The division of the skin and subcutaneous tissue well above the constriction is important, because it eliminates the edema, and prevents the formation of that hard infiltrated mass on the ventral surface of the prepuce that always occurs after a dorsal slit has been made. A liberal incision extending 3 to 6 cm. above the stricture will usually suffice. Hemostasis is controlled by heat and ligation of the bleeding points with single No. 0 plain gut. This procedure will give good exposure to the lesions, and enable the operator to do dark-field examinations, and to treat the primary lesions and co-existing infection. Incidentally, there will be fewer cases of suppurative inguinal adenitis, and less destruction of tissue. The wound should be dressed with the flaps in their natural position to prevent constriction at their bases. The penis should be elevated. Continuous application of hot Thiersch's solution will be found to be very efficacious in controlling the infection. After the lesions have healed, an acceptable circumcision can be done, under local anesthesia, by amputating the flaps at their bases.

*Submitted for Publication November 30, 1929.

TUBERCULOUS LYMPH NODES*

PRESTON A. WADE, M.D.

NEW YORK

LYMPH nodes when infected by the tubercle bacillus become enlarged and firm, are usually painless and are affected in chains or groups. They may reach a stage in their enlargement when they become stationary in size or may even recede, to enlarge again in a short time. The process may cease with a firm enlargement but commonly a secondary infection is superimposed and suppuration follows. When this stage is reached the fluctuant node may become reddened, painful and tender. Occasionally when treated expectantly, the suppurative process may disappear, but usually the course is progressive and unless incision and drainage is resorted to, the suppuration breaks through the skin and a sinus is formed which is long in healing. With this progressive disease of long duration the treatment is tedious and discouraging to doctor and patient, and the direction of the treatment is of utmost importance.

This condition is usually found in children and young adults, 71 per cent of Clute's series occurring in patients under the age of thirty. In this series, 65 per cent of the patients were female and 50 per cent of the cases were confined to cervical nodes.

The majority of patients affected with tuberculous lymph nodes seek medical help with the complaint of an unsightly tumor. The complaint of pain and tenderness is the exception. The surgeon is usually confronted with the problem of treating a young patient who demands a satisfactory cosmetic result with the loss of the least possible time.

GENERAL TREATMENT

Fortunately the diagnosis of tuberculous nodes is a comparatively easy one to make, and once made, the proper procedure is to institute careful and systematic

general treatment to increase the resistance and improve the health of the patient. The point is well known, but commonly slighted, and often a diseased node is conscientiously treated without success, while the poorly nourished host is neglected. Such simple measures as a carefully worked out diet, regulated rest, fresh air and sunlight should not be advised, but made a detailed part of the treatment. In most clinics cod liver oil is routinely given over a period of three to six months.

FOCI OF INFECTIONS

That the eradication of foci of infections is of great importance in the treatment of tuberculous nodes is not to be questioned. The teeth and tonsils are commonly considered the point of entrance of the tubercle bacillus. Davies-Colley and others think that tuberculosis results in a lymph node invariably as secondary to a pyogenic infection. In either case the foci of infection must be removed.

Diseased tonsils are undoubtedly causative factors in cervical tuberculous adenitis. Tonsillectomy may often be the only necessary operative treatment for the complete disappearance of the tumor. Tonsillectomy is of such prime importance in this condition that many surgeons advise it in all cases of cervical adenitis. The tonsils need not be apparently diseased, nor need there be a history of frequent attacks of sore throats or tonsillitis. It seems to be a matter of choice whether the tonsils are removed before or after a necessary excision of cervical nodes. This depends upon the stage of the disease in the nodes. In early cases without suppuration tonsillectomy would be advised pending decision as to radical excision. In the case of suppuration the local operative procedure should be ac-

* Submitted for publication November 23, 1929.

complished first. It seems unwise to attempt tonsillectomy at the same time as any cervical node operation although it is done with apparent safety in some clinics.

Other foci of infection, such as infected sinuses and external ear infections, should be carefully and energetically treated. The teeth are often symptomless harbingers of infection and should be carefully examined and x-rayed and abscesses and cavities eradicated. The scalp as a carrier of foci of infection is often overlooked, especially in children, whose pediculi may be the cause of continued scalp infection. The proper treatment of foci of infection is in a great measure responsible for the decrease in incidence of lymph node tuberculosis in the past decade.

LOCAL TREATMENT

There are two methods of treatment of tuberculous lymph nodes: (1) operative and (2) non-operative. Both are necessary and have their place in the proper handling of the case, the direction of the treatment depending upon the stage of the disease. The time element is often a question of importance to the patient and he may elect to undergo an operative procedure which will save time and expense, even though the chances of a cure by expectant treatment may be very good.

1. *Stage of Firm Enlargement.* During this, the early state of the disease, the choice of treatment is most important. It is at this period that the progress of the disease should be carefully watched, with the institution of the measures mentioned above. The lymphadenopathy may progress and recede in a relatively short time in the beginning stages and the patient usually demands local applications. Iodine and iodine salves seem to be most popular, but their usefulness is measured to a great extent by the psychic affect on the patient. Counterirritation is of doubtful value and care should be taken to warn the patient of skin burns. It is of course necessary to forbid any

local applications, especially those containing iodine, during the course of x-ray therapy.

Conservative treatment in the early stages of the disease is the wise procedure. Radical dissection has been given up as a routine procedure in most clinics because of the resultant unsightly scars and the chances of nerve and vein injury, and because of the usefulness of other conservative methods of treatment. Heliotherapy is of great value in the treatment of the lymph node involvement as is it in any other type of tuberculosis. Natural heliotherapy alone in selected sites is sufficient to cure tuberculous lymphadenopathy but when used in conjunction with other methods is most effective. The quartz lamp is valuable not only as for its general effect but also for its local application to the enlarged nodes.

X-ray therapy is probably the most valuable single conservative therapeutic agent in this stage of the disease. In Hanford's series the usual dosage was about one-third of the dose of filtered roentgen ray necessary to produce a slight erythema in an average person. The number of treatments was about ten, given over a period of four and one-half months. His results justify the use of x-ray in all cases during this stage of the disease.

Radium treatment has shown approximately the same results but its use is more troublesome and more expensive. Desjardins of the Mayo Clinic advises x-ray treatment as the method of choice, while Bowing, also of the Mayo Clinic, advises radium.

If the conservative method of treatment does not give results that are satisfactory the ultimate result is of course excision of the affected nodes. Hanford states: "When a small group of definitely enlarged glands has been present in the neck for two months or over, in a patient who has reached the age of five years or more, we believe that their early and complete removal is the safest and best treatment which can be instituted." Exci-

sion of the nodes of course assumes removal of all the diseased process but does not infer a radical dissection of a complete chain.

2. *State of Suppuration.* In this stage of the disease the treatment should be operative. Incision and drainage of a suppurating node, with removal of as much as possible of the diseased process, is the most effective procedure. Conservative treatment, such as repeated aspirations with injections of bismuth or iodine preparations, more often results in ultimate sinus formation than in resolution. Silcock describes a method of treatment by drainage with a linen thread but this and other similar methods are inferior to operative procedure. Some patients seek treatment for the first time with a suppurating node and demand conservative treatment, and in such cases we use at the New York Hospital Durante's solution as modified by Hitzrot, which is injected into the aspirated node. After incision and drainage of suppurating nodes the cavity is filled with this solution and the wound sutured in selected cases. The formula is as follows:

| | |
|----------------|------|
| Iodine..... | 1 |
| K.I..... | 1.5 |
| Guiacol..... | 5. |
| Glycerine..... | 100. |

For use in children 2 per cent guiacol is substituted.

3. *Stage of Sinus Formation.* X-ray treatment is found to be most effective in this stage of the disease and hastens the healing of wounds and sinuses. Heliotherapy is also of great aid in the healing of these wounds. When sinuses and open wounds are treated by x-ray the dressings should be simple. Hanford advises minute amounts of phenol in the sinuses with sterile petrolatum.

In the absence of x-ray treatment alternate dressings of balsam of Peru and the modified Durante's solution prove effective.

Sinuses of long standing which do not respond to such treatment need operation.

BUNION & HALLUX VALGUS*

ALFRED J. BUKA, M.D.

PITTSBURGH, PA.

THE subject of bunion and hallux valgus is presented with the aim of establishing the identity of each. It is believed that there are unquestioned evidences, as to type of pathology at the first metatarsophalangeal articulation, to be associated with each lesion. The cause of both conditions, as well as their non-operative correction will be considered. Either term is commonly permitted to imply the separate or combined pathology

of bunion and hallux valgus at this joint in almost any of its aspects. Albee¹ would consider the bunion and hallux valgus as synonymous and confined to abduction of the great toe.

To use these terms interchangeably for the mere pathological condition of enlargement and thickening of the bursa overlying the metatarsophalangeal artic-

¹ ALBEE. *Orthopedic and Reconstruction Surgery*. Phila., Saunders, 1919, p. 860.

* Submitted for publication December 4, 1929.

ulation is not correct. The word bunion is fittingly applied to such pathology, whether acute or chronic, but deformity

confined to the great toe; however, Da-Costa¹ considers the possibility of bunion over the same joint of other toes. The

FIG. 1. Miss G. Manifesting acute symptoms of bunion (bilateral). Condition overcome by corrective shoes.

in the location should not be included. The term hallux valgus, however, when used, should specifically imply deformity, a deviation of the great toe from the medial line to abduction. Ordinary hallux valgus is deformity which is secondary to an initial process, the bunion. It is not believed that there is either a congenital or hereditary predisposition to the bunion *per se*, although there is authority contrary to this opinion.¹

A bunion is a painful, acute or chronic inflammatory thickening or swelling of varying intensity of the synovial membrane and overlying soft structures at the first metatarsophalangeal articulation. Strictly speaking this lesion is primarily looked upon as a bursa, occasioned through continuous trauma from pressure and friction over the medial aspect of the metatarsophalangeal articulation of the great toe and without bony deformity. The disturbance, considered as such, is

practice among orthopedic surgeons is to apply this term to an indefinite pathology at the metatarsophalangeal articulation of the great toe.

The bunion, when of the acute type, presents the following symptoms, appearing in about this order: First, pain on pressure, sometimes with fluctuation over the joint involved and pain with great discomfort during efforts at use; second, swelling over the joint which may further be associated with contusion evidences such as redness, abrasions and ecchymosis; third, the possible finding of a nidus for the development of infection. The predisposition to breaking down of the soft structures, overlying the bursa of the articulation, through friction and pressure must be apparent. Thus, when these soft structures give way, and with the susceptibility of this site to infection as well as dissolution, the simple bunion may become a severely serious issue. Operation might

¹ MOORHEAD. Traumatic Surgery, Phila., Saunders, 1917, p. 133.

¹ DA COSTA. Modern Surgery. Phila., Saunders, 1908, p. 653.

then be necessary even without any sign of valgus deformity.

Hallux valgus is an outward or abduc-

tion deformity of the first metatarsophalangeal articulation, of varying degree, the great predisposing factor being the bunion.

Where the problem of severe deformity

FIG. 2. Mrs. S. Severe type of hallux valgus with contractures (bilateral).

tion deformity of the first metatarsophalangeal articulation, of varying degree, the great predisposing factor being the bunion. The term hallux valgus implies abduction from the medial line or displacement of the great toe toward the other toes. It does not in any manner identify itself with what is understood by the term bunion. Hallux valgus as a deformity becomes an issue for correction according to its severity. The deformity itself, so long as it is not aggravated by an acute bunion, is often not of the painful type and as such may not require correction for the comfort of the patient. Frequently only because of the fact that one is unable to wear ordinary shoes with comfort, is operation considered. Where, however, severe symptoms are involved with this deformity, operation is the surest and best means for relief and correction. Hallux valgus of the moderate type may readily respond to corrective measures without operation through proper footwear and may possibly be further overcome with night splintage. Such measures can be facilitated by the patient who

occurs, often involving dislocation of the proximal phalange of the great toe, with difficulty in ambulation, operation becomes the most certain method for correction. Hallux valgus can be so readily prevented by overcoming the predisposing factors of bunion that there is no excuse for the existence of the condition. The bunion may swing toward the development of a hallux deformity but correct shoeing with time will readily overcome the tendency. The general impairment of gait occasioned from these lesions is so simply corrected with proper footwear that it is disappointing to see how the wearing of improperly fitted shoes is permitted to continue. This factor alone leads ultimately to the ever-increasing pathological problems of the fore part of the foot.

The chief contributing factor to the development of the bunion is faulty footwear and the predisposing factor to the development of hallux valgus is the bunion. Short fitting hosiery will encourage and aggravate these conditions but the main or common cause is improper shoeing. Shoes which are too lightly constructed

for proper weight-bearing and walking predispose to trauma of the digits. Then, too, because of the short shoe with high

langeal articulation. With continued wearing of a faultily constructed and short-fitted shoe the tendency to abduction of the great

FIG. 3. Mrs. S. After correction by operative procedures

heel worn by women or the short shoe with narrow toe worn by men in their efforts to make the foot appear stylishly shod, there is a general tendency toward crowding the foot into an undersized shoe. Wearing such shoes bunches together the toes so that there is more or less abduction of the great toe with overlapping or underlapping of the second toe. There are also not uncommonly varying degrees of injuries with resultant pathology to the crowded digits. The commonest developments from such factors are inflammatory changes, contractures, deformities and callosities. Of this group the callosity, the simple corn or clavus, whether of the hard or soft variety, is most heroically endured.

From the crowding of the foot into the short shoe with the high heel or the short shoe with the narrow toe, there ultimately develops a permanent deformity of the toes and, more particularly for our consideration, of the first toe at the metatarsophal-

angeal articulation. With continued wearing of a faultily constructed and short-fitted shoe the tendency to abduction of the great toe goes on uncorrected and without the needed consideration. At this particular stage correct shoeing may readily overcome deformity and it is almost certain it will relieve the acute inflammatory process of bunion since by the discontinuance of pressure the exciting cause is removed. One possessing such a lesion cannot wear a physiologically correct shoe of the same size as the stylish type to which he has been attached. Instead of recognizing the mistake and desiring that the foot be placed in proper alignment with a correctly built and fitted shoe, the subject will endure the discomforts and harm subsequent to wearing popular shoes of stylish type. The impossibility of holding the great toe in the medial line becomes a problem because of the fact that the inflamed and swollen bursa over the medial aspect of the "bunion joint" will be too acutely involved to permit a correction. Then too the toe cannot assume the proper

alignment so long as the deformity is encouraged and maintained by the wearing of an improperly constructed and fitted shoe, from the viewpoint of anatomical structure. As this deformity continues, aided by support, inflammation of severe and deep character develops, and with further abduction of the great toe at the "bunion joint" the resultant deformity, hallux valgus, becomes a serious complication.

Thus, stimulation to bony formation through irritation about the distal metaphysis of the first metatarsal bone prevents any possible alignment with the former articulating proximal phalange. An apophysis or exostosis on the medial aspect of the joint is the result of this irritation and this spreading bony excrescence brings about in the extreme cases ultimate dislocation of the proximal phalange from the first metatarsal bone. It is this deviation outward from the medial line, whether of mild or severe character, which constitutes the lesion that should be identified by the term hallus valgus.

There is no reason for considering bunion and hallux valgus as one and the same lesion any more than there is for

identifying bunion with hallux varus, hallux extensus, or hallux flexus.

In brief it is desired to stress the fact that with proper footwear it is readily possible to overcome the formation of bunion and the ultimate development of hallux valgus. Further that the bunion usually finds origin from the predisposing factors: short hosiery, short shoes with high heels or short shoes with narrow toes. Also, that the common sequel from a bunion left unattended is hallux valgus, which deformity may present advancing pathology, encouraged through the continued wearing of improper shoes. The ordinary bunion is readily corrected without operation while hallux valgus, as a complication or sequel, is a genuine deformity which cannot be overcome without operation, unless it be of the moderate type. About 90 per cent of all adults are sufferers from some sort of foot trouble most of which can be prevented by proper shoeing. People refuse to realize that most of this distressing list of disturbances originates from the wearing of improperly constructed and improperly fitted shoes.

WOUNDS OF THE SCALP AND FACE*

EDMUND BUTLER, M.D.

SAN FRANCISCO, CALIF.

ONE room in every office should be equipped for the care of emergencies; a supply of dressings, sterile instruments, and sterile threaded suture material, arranged on a small portable table ready for immediate use, is the minimum any doctor should offer his community.

The injured person must be placed supine on a comfortable table immediately upon arrival, regardless of the slowness of the injury. Repair of wounds and painful dressings must not be done with the

patient sitting upright. Aromatic spirits of ammonia and whiskey are useful in avoiding an attack of syncope.

Cover the wound with a sterile dressing large enough to overlap the uninjured skin 1 to 2 cm. Make firm pressure with the fingers of the left hand to control bleeding. Wash the remainder of the face or scalp and hair free of blood with a wet towel; the wetter the towel the easier the blood is removed. Raise the sterile dressing, beginning at one angle of the wound, clamping bleeding vessels as they

* Submitted for publication December 12, 1929.

appear. Lift up the edges of wound and make a careful inspection of the depths, removing clots with smooth dressing forceps or by irrigating with saline, sterile water or weak peroxide solution. The author favors irrigating with weak peroxide solution because it makes foreign materials more easily identified and fracture line stand out clearly. Frequently the scalp has been stripped up for several centimeters, secreting various amounts of foreign material.

The mechanical cleansing of the wound is far more important than the liberal and blind use of antiseptic solutions. The relative merits of iodine, mercurochrome, aniline dyes, hypochlorite solution, ether, benzene, and picric acid as bactericides depend upon the care with which the wound has been mechanically cleansed and not upon their relative antiseptic qualities. The wound after inspection and removal of foreign material is flooded with any of the antiseptic solutions, iodine 3 to 7.5 per cent being the most frequently used. If any vessels continue to bleed, fine catgut ligatures are used, and if vessels have retracted and cannot be controlled with clamp, it may be necessary to use ligatures mounted on needles traversing the region of the vessels and tied just tight enough to control bleeding and not strangling all tissues in the grasp of the suture.

Now we are ready for suturing. Fine silk gut, black silk, horse hair, or Michel clips may be used. Michel clips are of very little use in the dense scalp but most useful in the frontal region and wounds of the upper face. If the wound is irregular, the angles are approximated first, the suture taking in the entire thickness of the skin. The deep fibrous layer is the layer that presents future spreading of the scar. One suture to 2.5 cm. is sufficient in the hairy scalp. In the face, sutures must approximate the skin accurately. It is a very sane procedure to drain all scalp wounds with small pieces of rubber band or twisted silkworm gut. Wounds of the face, if irregular or pocketed, should also be drained. All drains to be removed at

the end of twenty-four to forty-eight hours if infection has not developed. An excellent dressing is compresses of equal parts of glycerine and alcohol. The compress is covered with oil silk, gutta-percha tissue, silkoid, or oil paper. Drainage is promoted and crusting impounding exudate is prevented. Wounds must be dressed daily until you are sure infection is not present.

An immunizing injection of tetanus antitoxin is given in all lacerated wounds where the subcutaneous tissues are invaded. The extent of the wounds is no indication of the likelihood of tetanus bacillus contamination. A small wound may harbor tetanus bacilli. Lacerated wounds ground full of street filth should not be sutured but drained and allowed to heal by granulation.

Hair washed with equal parts of ether and benzene is sterile and shaving need not be done in the scalp or eyebrows unless the hair interferes with approximation. One must always remember no matter how slight the scalp injury may have been and even though there is no apparent intracranial injury, that a fissure fracture of the skull across one of the meningeal arteries may exist and spell future disaster if not carefully watched.

Wounds of the scalp and face heal rapidly, and infection is not likely to occur, because of the abundant blood supply. In wounds of the cheek or lips entering the mouth, the sutures should include the skin muscles and submucous down to, but not including the mucous membrane. Approximate the mucous membrane with fine silk sutures. If the Stenson's duct is cut across suture the skin carefully, do not close the mucous membrane in the region of the duct, thus allowing a fistula to develop into the mouth and not externally on the cheek.

Too much foreign material, glass, splinters, metal, paint and enamel, is closed up in wounds of the scalp and face. Careful hemostasis, followed by careful inspection and mechanical cleansing is the only way to avoid this inexcusable error.

TREATMENT OF GRANULATING WOUNDS WITH DELAYED HEALING*

NELSON W. CORNELL, M.D.

NEW YORK

THE stages of repair in a wound which heals by granulation tissue are as follows:

1. An abundant exudation of small round cells, whose function is to remove dead or damaged tissues, and also to break up, disintegrate, and finally absorb any blood clot.

2. The invasion of the wounded area by fibroblasts from the tissues composing the parts.

3. Vascularization by protoplasmic buds growing out from the capillaries. These soon become canalized and lined with endothelial cells. The capillary loops thus formed give the granular appearance to the developing tissue.

4. Cicatrization and epithelization: In this stage the fibroblasts become spindle-shaped with collagenous material around them. This gives to the wound contractile properties which tend to make the wound smaller and also lift the underlying tissues toward the surface, making the wound less in depth. This property of contraction also acts to constrict the vessels in the granulation tissue, causing, them to disappear. When the entire surface is covered with epithelium the wound may be considered as healed.

There are numerous conditions under which granulation tissue grows, which may alter the character of the granulations to such an extent that the wound will not heal. Some of the more common of these conditions are:

1. Lack of rest in the part affected. Rest is an essential factor in the treatment of granulating wounds, and if the tissues are constantly being stretched it is quite often impossible to heal them. For example, granulating areas over extensor and flexor surfaces of joints are most difficult to heal if the part is not immobilized.

2. Irritation by rough, unsuitable dressings, or irritating chemical agents which may be used in the dressing.

3. Unhealthy or devitalized condition of patient's tissues, as in badly bruised or lacerated skin, or in locations where there is persistent venous congestion, which prevents access of healthy blood. An example of the latter is well demonstrated by varicose ulcers.

4. Constitutional disease, such as Bright's disease, diabetes, syphilis, scurvy or alcoholism, severe anemia.

5. Infection.

6. Foreign bodies.

The treatment of wounds which will not heal due to the formation of granulation tissue is:

1. Constitutional: in which any severe constitutional disease is sought for and treated accordingly. In diabetes, for example, diet and the proper administration of insulin are used.

2. Local:

- (a) Application of medicinal agents which may cut down excessive growth of granulations, or may stimulate inactive growth or clear up a low-grade infection.

- (b) Surgical: Where a cicatrizing base of a granulating area is preventing it from healing, excision may be done and the freshened edges loosened and brought together, or skin grafting done as indicated. In cases of venous congestion due to varicose veins the latter may be excised, or treated by the injection method, i.e., injection of the veins.

First of all in granulating wounds which do not heal, constitutional diseases should be ruled out, but if found should be properly treated.

Next, one often encounters an exuberant overgrowth of normal pink granulations which have grown so far above the surface

* Submitted for publication November 23, 1929.

of the adjacent skin levels that it is impossible for epithelium to grow over the granulating bed. In these cases, repeated "burning down" to skin level by the application of silver nitrate caustic stick at intervals as indicated, will usually suffice to cause a rapid epithelialization of a wound. Not infrequently the granulating bed may present healthy granulations but be of such a diameter that it is quite impossible for the epithelium to push across the space. In these cases pulling the edges of the wound into closer proximity by adhesive strips is often sufficient. Another very excellent use of adhesive in this type of wound is placing $\frac{1}{4}$ inch strips of sterile adhesive around the edges of the wound extending out into the granulating bed from the skin edge. In twenty-four hour's time the advance of epithelium under the strips can be recognized by the naked eye and by a continuation of the same process often very large granulating areas are covered over by new skin.

An example of excessive overgrowth of healthy granulations is well illustrated by a patient who had a scalp wound which would not heal, following a fracture of the skull. When I saw her several months later there was a mass of granulations tissue piled high so that it resembled a medium-size mulberry as to size and appearance. As it was clipped off with scissors a small sized artery was found extending up into it. Following the removal of this mound of granulation tissue, the healing-over process took place rapidly.

A chronic low grade infection may cause an exuberant growth of unhealthy granulation tissue. The granulations then take on a paler or grayish appearance which heap up and overhang the skin edges. There is usually a considerable whitish purulent discharge and the wound refuses to heal. This type of granulation is best treated by wet dressings until the infection is overcome, followed by use of the caustic stick, together with some mildly disinfecting and stimulating agent, such as balsam of Peru, dichloramine T, mercurochrome ointment, etc.

Foreign bodies in a wound, such as an unremoved suture, spicule of dead bone, a small piece of gauze or rubber drain, or in hand infections a piece of dead tendon, will cause an overgrowth of grayish, unhealthy appearing granulation tissue. Prompt healing follows removal of the foreign substance.

In contradistinction to exuberant granulations, there are the underdeveloped or insufficient granulations. Provided constitutional disease has been ruled out, this type of granulation tissue needs stimulating. Balsam of Peru is probably foremost among the non-irritating stimulants. There are numerous others, such as dichloramine T, Durante's solution, etc.

Physical agents are also useful. The simple therapeutic lamp consisting of a heat-giving bulb applied for fifteen minutes three times daily is most efficacious in promoting growth of sluggish granulations. Other light therapy such as the infra-red, or ultraviolet lights are useful but should be used with extreme caution and by an experienced person.

Heliotherapy, which is cheapest and most often accessible, is oftentimes completely forgotten. Subnormal granulation tissue when exposed to the direct rays of the sun is always benefited by the exposure, and healing is hastened. The patient can do this frequently at home between visits to the doctor. It must be impressed upon the patient, however, that the exposure should be direct and not through a window pane.

Constricting by voluminous dressings should be avoided, the aim should be to give as free an access of air to the granulating area as is compatible with good wound asepsis.

Under the class of deficient granulation tissue as a cause of wounds not healing, probably the foremost offender is the varicose vein ulcers in the lower extremities. Due to the constant venous congestion these ulcers at times will actually spread instead of healing. The most efficient non-operative method in this type of case is the application of the so called

ACE (all cotton elastic) bandage. This is applied in the morning before the patient gets out of bed, and is worn all day. Many of the smaller sized ulcers of this type will heal quickly under this treatment. Elastic stockings should never be used as they constrict at the top and the bottom, adding to the venous congestion rather than relieving it. They also can be extremely uncomfortable. For the larger, long-standing, more callous ulcers with cicatrized base, surgical removal of the veins is indicated, or better still, the injection method which is fast displacing the surgical procedure.

Wounds caused by chemical burns, severe bruises, etc., which cause a deep loss of tissue and heavy "scab" formation,

are best treated by wet dressings of saline until the slough comes away.

Among the mildly stimulating ointments for this group of sluggish wounds is 5 per cent ammoniated mercury, boric acid and zinc oxide ointments.

In conclusion it may be said that wounds which will not heal, due to the formation of granulation tissue, fall into two great classes, the overgrowing granulations and the deficiently growing granulations. In the first group a cutting-down of the overgrowth or removal of the cause of this overgrowth is indicated. In the second great group the granulations must be stimulated and encouraged by the application of the physical and physiological principles indicated.

THE RÔLE OF LOCAL ANESTHESIA IN OFFICE PRACTICE*

ROBERT EMMETT FARR, M.D.

MINNEAPOLIS, MINN.

CONSIDERED from the standpoint of anesthesia alone, the office equipment of different physicians varies widely. Obviously what might apply to one would have no application to others. Few physicians realize the ease with which any office may be equipped with the necessary paraphernalia required for the routine employment of local anesthesia. Once the equipment is installed and the fundamentals of technic mastered, the bugaboo that the use of local anesthesia is a complicated process fades into obscurity. Furthermore, when the physician has his office so equipped and realizes the advantages that may accrue from the routine use of local anesthesia in office practice, he will be surprised at its many advantages and, as a rule, wonder how he formerly carried on without this important adjunct.

Regardless of the type of work a physi-

cian does, general practice or specialization, rural or urban, there is one fundamental principle that should always be his guide. The interests of the patient should transcend all others. Even the application of the slogan "the greatest good to the greatest number" must never be allowed to interfere with the application of this principle. Every individual patient should receive the benefits to be derived from following this maxim. Time, expedience, decreased income, the physician's comfort and every conceivable factor must be considered secondary in importance to the patient's interests.

Advantages. With the above considerations in mind there are many advantages to be gained by the employment of local anesthesia whenever it is indicated. Incidentally, its use corresponds in a marked degree with the patient's interests, expedience and many other important points.

* Submitted for publication December 12, 1929.

From the patient's point of view, there is usually a great difference between a visit to the hospital and the office. In the absence of an emergency this difference is often sufficient to cause the patient to delay or avoid treatment rather than go to the hospital. It is my experience that many patients who will not consider entering the hospital will consent to a minor operation in the office. Thus, the fact that the physician is prepared to perform minor surgical procedures at the office will, in many instances, bring elective minor surgical cases to operative treatment which otherwise might not come at all. The association of the hospital in the minds of the laity with confinement to bed and expense contrasts markedly with a trip to the physician's office and an ambulatory convalescence.

Again, there is a large borderline class of cases which, depending upon the choice of the physician, may receive treatment at either hospital or office. Most people, however, prefer the latter. The advantage of local anesthesia may manifest itself in another way. Those with known surgical conditions, as minor skin or rectal lesions, may present *earlier*, provided they believe that they can be treated at the office. Indeed some of these, if confronted with a trip to the hospital as the only alternative will refuse succor. Nor infrequently those who, for the reasons mentioned, go to the office, may be prevailed upon to go to the hospital for an operation should it be deemed necessary, whereas had they not expected that they could be treated at the office, they might not have presented at all.

Another advantage of the constant and proper use of local anesthesia in office practice is its aid in making painless examinations, or instrumentations, especially those associated with the bladder or urethra. In regard to this point, it has been my observation that few physicians would think of inflicting upon a patient an examination, or any kind of instrumentation, that would result in loss of consciousness, but even in this epoch,

some physicians still insist upon passing urethral sounds in the male without first anesthetizing the urethra, with the result that an occasional patient faints on account of the pain. The pathological rectum or anus, when acutely inflamed, is likewise all too often examined without anesthesia, the patient being caused needless torture. It is obvious that the more attention there is paid to the use of local anesthesia in office practice, the less will be the suffering of the sick and the more incentive there will be for patients to attend to their ailments.

Equipment. The equipment required for employing local anesthesia in office practice is simple and yet, if the physician expects to meet the indications and he and his patients are to derive the full benefits of the method, careful thought must be given to the armamentarium.

Off-hand, one might think that a syringe, some needles and an anesthetic solution are all that are required in order to employ local anesthesia in office practice. As a matter of fact, these essentials are but a portion of the necessary equipment and the choice, preparation and care of these is exceedingly important. Provided one wishes to obtain the maximum advantage of local anesthesia, attention must be given to the adjuncts its use demands at the office as well as the hospital.

The psychic aspect of the subject must not be overlooked and while preliminary hypodermic medication is seldom indicated or advisable in office practice, everything possible should be done before and during the examination or operation, to allay the patient's apprehension and insure comfort and confidence.

A most important dictum is that no patient should be given novocaine by injection while in the upright position, provided the drug can be administered with the patient reclining. Also if the drug is injected with the patient in the upright position, facilities should be at hand to allow the assumption of the prone position without the slightest delay. So-called

idiosyncrasies to novocaine, while extremely rare, probably do exist and as patients not infrequently faint from other causes, which produce cerebral anemia, the treatment of both conditions demands the prone or inverted position.

In our experience, ether is the most satisfactory antidote to novocaine. Caffeine is recommended but the few slight reactions we have seen subsided before this drug could be administered. It is our opinion that ether should be at hand and administered at once in case a patient shows a serious reaction. Caffeine, when used, should be given intravenously and in a large dose: 7 grains. These drugs are as much a part of the necessary equipment as are syringes and should be in readiness before the local anesthetic is administered. Slight reactions require only the head-down positions for a few moments. It is probable that the majority of these reactions are due to cerebral anemia and have no relation to the toxicity of novocaine. A few inhalations of ether are stimulating in any case and do no harm.

Sterilization. The sterilizing basin should be square and may be used as an instrument tray during the operation. At least two good syringes, preferably of different sizes, (5 and 10 c.c.), should be prepared by boiling in distilled water. A number of needles, in sizes corresponding to the demands of the case in hand, should be sterilized with the syringes. Two small containers of glass or metal and graduated in cubic centimeters should also be sterilized. The drugs required may be sterilized with the syringes and instruments, being placed in one of the containers which is partially filled with water. Corresponding to the amount of solution required, a number of Ringer's tablets are dropped into the solution before boiling. With one of the syringes a sufficient amount of water may be added after sterilization to bring the solution to the proper level. Epinephrine tablets, if used, may be added before sterilization, but if adrenalin chloride is used it should be added to the solu-

tion *after* sterilization by means of a sterile medicine dropper. This procedure may be considered safe as repeated bacteriological tests have been found negative. A more simple method is to keep on hand a "stock solution" of novocaine in Ringer's solution (2 to 4 per cent) in a sterile bottle and dilute it as desired. Such solution may be kept from four to six weeks, and probably much longer, without deteriorating although it may take on a light brownish color. Solutions that are dark brown should not be employed. Careful cleaning of the syringes and needles after using is important. The needles should be flushed with alcohol or ether, then with air and the lumen coated with a thin oil.

Quinin and urea hydrochloride in a strength of 1:600 should be used in all granulating wounds as a prophylactic against pain. Its preparation is similar to that of novocaine.

Anesthesin should be employed preliminary to all throat operations, one tablet being dissolved in the mouth thirty, twenty and ten minutes before operation. A novocaine suppository (4 per cent) should be inserted in the rectum one-half hour before making a proctoscopic examination. In case the necessity of an operation is apparent, the rectal examination should be postponed until after anesthesia has been established by a sacral block or by infiltration. By following this plan much suffering may be avoided.

Brachial anesthesia may be employed at the office and under its influence emergency or elective operations upon the upper extremity may be performed. Even dislocations of the shoulder and elbow may be reduced under this type of anesthesia.

For the passage of a catheter or sound the instillation of 4 per cent novocaine solution, to be retained for a period of fifteen to twenty minutes, is satisfactory except in the case of complicated strictures, which are best treated at the hospital and under sacral anesthesia.

Cystoscopic examinations may be made routinely at the office but this requires

special equipment, x-rays, etc. and should not be attempted in the absence of complete equipment. Furthermore except in "repeaters," sacral anesthesia is the method of choice for cystoscopy and few offices are properly equipped for the induction of this type of anesthesia. Therefore, unless the equipment is adequate and a well-trained corps of assistants available, sacral anesthesia should be reserved exclusively for hospital practice.

All types of minor surgery may be performed at the office under local anesthesia. The difficulty of maintaining asepsis is a more important reason for sending patients to the hospital than is the difficulty of administering satisfactory local anesthesia.

In an office equipped with x-rays, fractures, with the possible exception of those of the lower extremity, may be reduced under local anesthesia. In the upper extremity brachial anesthesia, conduction anesthesia, or a transverse infiltration block are entirely satisfactory and the patient may become ambulatory in about two hours. In such cases, anesthesia may be established, the physician may go on with his other work for fifteen or twenty minutes, while the anesthetic solution is disseminating, and then reduce the fracture. A qualified nurse should be in charge of the patient the while. Anesthesia will endure sufficiently long to permit the repeated making of roentgenograms.

The properly equipped office therefore compares favorably with the hospital for this type of work, whereas, with general anesthesia this is not true. Among the other conditions that can be treated under local anesthesia are: Many varieties of lacerated wounds, skin tumors, the removal of foreign bodies such as needles from the tissues, the removal of foreign bodies from the eye, the injection of the sciatic nerve with quinine and urea (in these cases the patient may ride home and remain quiet for a day or two).

The physician who handles a considerable amount of industrial surgery will find it well worth-while so to equip his

office that a wide variety of wounds, muscle and tendon suture, amputations and plastics about the hands may be done under local anesthesia. I may say that we have carried out all of these procedures at the office under local anesthesia but, I repeat, careful preparation for all anesthetic emergencies was made. Therefore, as stated, he who essays to do this type of work must make adequate preparation for it. The outlay is not great but everything should be in readiness to meet the requirements. Once a system is established, it soon becomes routine and the physician who prepares his office for this routine will be surprised at the scope to which local anesthesia can be employed in office practice and likewise astonished at the satisfaction that will be experienced, not only by him but his patients as well.

The anesthesia technic in office practice differs in no wise from that used in hospital practice. The same attention to *finesse* is required in both. Borderline cases, when it is practicable, should be sent to the hospital.

Regardless of what may be the relative merits of local and general anesthesia in hospital practice, local possesses many advantages over general as an office anesthetic. Thus the general practitioner, who may be situated far from hospital facilities and a good anesthetist, may increase his usefulness and the scope of his activities, by familiarizing himself with local anesthesia technic and equipping his office for its employment. Likewise the surgeon or surgical specialist may offer to his patients many of the advantages mentioned above and if fortified with an assistant, an office nurse and x-rays, may perform cystoscopies, tonsillectomies, reduce fractures, treat surgical lesions of the skin and rectum and a variety of industrial injuries.

SUMMARY

The scope of local anesthesia in office practice may be made comparatively broad. Its use has advantages that are both economic and psychic. It is of special

advantage to the isolated practitioner of medicine who lacks hospital facilities. Its use demands special training and equipment and no one who is not prepared to employ it skilfully should essay its use.

With proper training and equipment local anesthesia may be employed in office practice with a great deal of satisfaction to the physician, surgical specialist and their clientele.

THE PREVENTION OF CICATRICAL CONTRACTIONS*

JOHN H. GARLOCK, M.D., F.A.C.S.

NEW YORK

THE degree and extent of cicatrix formations depend upon a number of known factors and an unknown number of less apparent ones. Thus, in a consideration of cutaneous burns, the surface area involved and the depth of the tissue injury will govern the *extent* of the subsequent scarring. Wound infection plays an important part in repair processes and influences to a large extent the *degree* of scar tissue formation. Clean wounds heal with minimum scarring. The converse is likewise true. In addition, clinical experience indicates that certain microorganisms produce more tissue destruction than others, thus influencing the extent of the subsequent cicatrix. The anerobic bacteria are peculiarly the offenders in this respect.

Less apparent factors must surely be operative in determining the degree and extent of scar tissue formations. It is difficult to explain why some patients produce large scars with cicatricial contraction resulting in deformities, while others, with practically the same wounds, will show little tendency to scarring and no indication of deformity. The reasons for this marked difference in individual response are not known, but will probably be found in the future through further studies in tissue physiology and tissue chemistry. From a preventive standpoint, likewise, little is known which would aid in forestalling the development of

extensive cicatrices in patients who, from previous experiences, are known to be susceptible to this tendency.

The anatomical site of the original wound or injury governs the development of a cicatrix which will contract so as to produce deformity or interference with function. Extensive wounds, especially burns, involving the neck, lips, angles of the mouth, eyelids, the axillary folds, the popliteal regions, the antecubital fossae and the fingers, will very often result in serious deformities, unless measures are taken to prevent such sequelae. Even then the outcome may not be a happy one. In considering the healing response of the various regions of the body enumerated, certain axioms, more or less true, may be enumerated. Second and third degree burns involving the eyelids will produce cicatricial contractions resulting usually in ectropion of one or both eyelids. Extensive injuries or burns about the mouth and lips will often cause bizarre cicatrices changing the entire facial expression, interfering with the functions of the lips or producing ectropion of the lips. In the latter condition, the constant drooling of saliva is a particularly distressing complication. Deep burns of the neck during the process of cicatrization produce a very disfiguring deformity whereby the chin is drawn down toward the chest and extension and rotary movements of the head are greatly impaired. Burns involving the

* Submitted for publication October 26, 1929.

axillary folds form cicatrices which bind the arm to the side of the chest and prevent abduction at the shoulder, a serious functional disability. The flexor surfaces of the various joints of the extremities are especially vulnerable from the standpoint of cicatricial contractions and the subsequent development of flexion contractures.

In considering the prevention of cicatricial contractions, the surgeon must consider the effect on form and function of the wound he is about to make with his scalpel. This is especially important in the surgery of the face, neck, axillae and extremities. The surgeon should be familiar with the anatomy of the "lines of the skin." These "lines" indicate where skin tension is greatest, where relaxation occurs, where natural cutaneous wrinkling is situated and serve as a guide to the proper placing of incisions, their direction and extent, with a view to producing minimum subsequent scarring. For instance, a median vertical incision in the neck should rarely be made. The tendency toward a flexion contracture is considerable. Again, one should never make an incision at right angles to the flexion creases of the joints of the extremities, especially of the fingers. This might very well be considered one of the ten commandments of surgery. An incision made over the front of a finger so as to cross the flexion creases at right angles will nearly always produce a flexion contracture. The proper site for a finger incision is on the anterolateral aspect. For greater exposure of the deeper structures, it may have a right-angled extension running parallel with a flexion crease.

In dealing with injuries and wounds of the regions of the body already enumerated, the surgeon must constantly bear in mind what effect the subsequent scarring will have on form, and especially, function. In wounds of the extremities, measures must be taken to prevent contractures of the flexor surface of joints. The judicious use of splints or of the principle of traction and suspension during the process of healing ranks foremost. Thus, a knee should be

kept in extension during the healing of a burn in the popliteal space. The head should be kept in extension during the convalescence following a burn of the neck. Burns or wounds with loss of skin involving the axillae call for wide, full abduction at the shoulder until healing is complete. The surgeon should be particularly solicitous of wounds of the flexor surfaces of the fingers because of the ease and rapidity of the development of contractures. Intermittent splintage in extension is the method of choice. I say "intermittent" advisedly, because finger joints become stiffened easily with continued immobilization. Or, one may make use of the principle of elastic traction by the employment of a banjo splint with rubberband traction of each finger. This permits of continuous extension.

Often the surgeon is confronted with a large granulating wound, following a burn, for instance, which presents a constantly weeping surface and which promises a prolonged convalescence. During the process of epithelialization of such a wound by the growth of epithelium from the sides, considerable fibrosis of the underlying tissues takes place and the chances for cicatricial contraction are greatly enhanced. The early application of Thiersch grafts to such a wound as soon as the appearance and bacteriology of the granulations permit, brings about early healing and, what is more important, a minimum of the underlying fibrosis. Very often, indeed, with the parts placed in over-corrected positions, no contraction of the scar will occur. Should contraction develop, however, the procedure has accomplished a considerably shortened convalescence with rapid healing. The more general adoption of this procedure emphasized by H. H. M. Lyle, is recommended as one of the important aids in the prevention of cicatricial contractions. The subsequent application of pedicled skin flaps or the performance of various plastic operations must be considered for the relief of scar contractions, should they occur.

OFFICE TECHNIC OF CERVICAL BIOPSY*

M. GLASS, M.D.

BROOKLYN, N. Y.

THE early diagnosis of malignant neoplasms is the most important item at the present time, and nowhere is this necessity greater than in the cervix uteri. When one considers that over 50 per cent mortality still persists with the most modern therapeutic measures used, and that carcinoma of the cervix is the most common of all malignant tumors in women, there appears only one way to combat this deplorable situation, and that is by recognition of the process in the early stages, depending not only on our diagnostic acumen, but also looking to the microscope for aid. This necessitates doing more frequent biopsy studies of suspicious lesions.

Erosions of the cervix are by no means as innocent and unimportant as they look, for they not only frequently serve as a starting point for a carcinoma, but may also present, to all intensive purposes, a benign-looking lesion behind which an early carcinoma is gaining a fatal headway. So too, the small pedunculated polyp, protruding through the external os of the cervix, may be and not infrequently is the seat of an early myosarcomata of the cervix.

Bearing these two possibilities in mind when examination of the cervix presents such a condition, this examination is not complete until a biopsy has been done, and this simple procedure can be safely and aseptically done in the office.

The procedure is as follows: With the patient in the knee-chest position and using a Sim's vaginal speculum which elicits the best exposure of the cervix, though good exposure can be obtained with the patient in the lithotomy position, and a bivalve speculum in place, the vagina and cervix are gently swabbed with cotton until dry; the cervix and upper third of

the vagina are painted with 3½ per cent tincture of iodine. Into the cervical polyp, or into the suspicious zone of cervix a single hook tenaculum is inserted to steady the cervix or polyp and afford the operator a point of leverage. In the case of a polyp it is advisable to be very gentle in the traction so as not to tear the polyp off its attachment because of the danger of hemorrhage, but to use a moderate amount of tension and then with a cautery tip at a cherry-red heat slowly transect the pedicle until the polyp has been severed. The heat from the cautery safeguards against hemorrhage by coagulating the blood vessels cut across.

In the case of the cervical lesion, into which a tenaculum has been inserted, using a sharp knife, a small wedge of tissue is removed about 1 cm. on each side. Then gently sponge the bleeding surfaces dry and cauterize the raw areas with the cautery tip at a cherry-red heat until all bleeding has ceased. Following both procedures a tampon soaked with 4 per cent mercurochrome is placed flush against the cervix. The tampon is left in situ for at least twelve hours, serving two purposes, i.e. as an antiseptic, and to aid in hemostasis if the cauterization has been inadequate.

The specimen should be immediately placed in a test tube containing 10 per cent formalin and dispensed to a competent pathologist for microscopic study.

In conclusion one must remember that:

1. Gentleness with tissues suspected of being malignant cannot be too strongly emphasized, for trauma in any form favors metastases.

2. All instruments must be sterile.

3. The knife must be both thin and sharp to minimize the trauma.

4. The cautery at a cherry-red heat is used to seal off all lymphatic and blood

* Submitted for publication December 12, 1929.

vessels which are cut across, thus preventing metastases and also eliminating the possibility of an open, free wound from becoming infected; for infection runs hand in hand with trauma in the spread of this disease.

THE BUBO*

H. H. GOLDSTEIN, M.D.

NEWARK, N. J.

CONTRARY to general belief that a bubo is an inflammatory reaction of the inguinal glands, any lymphatic gland which is undergoing inflammatory changes is a bubo. The etiology of the inflammatory reactions is, of course, multitudinous and presents a most difficult and at times, baffling diagnostic problem. It is not so much a question of the treatment of the lesion, which we will soon consider at greater length, as it is of differential diagnosis. At times the diagnosis can not be made and the lesion is consigned to the waste-basket or "granulomas."

A patient comes to the office complaining of a "lump" in the groin. It is hard, firm, and painless or it is red, inflamed, painful and tender. Or the enlarged gland may be found during the course of the physical examination, apparently symptomless. Another patient comes in presenting a ragged ulcerating lesion in the groin, perhaps painful usually necrotic, secondarily infected, and discharging purulent material. Effective treatment can be instituted only after a diagnosis is made.

The buboes resulting from tropical sore, bubonic plague, oriental plague, actinomycosis, glanders etc. are so rare that they need not be discussed in a paper of this nature. The common garden variety of bubo claims our attention first and perhaps the most common of all is the bubo consequent on gonorrheal or chancroidal infection.

The swelling of the inguinal glands during the course of gonorrheal infection

may come on shortly after the onset of infection or some years afterward. Usually a focus of infection still remains in the seminal vesicles, prostate or epididymis which feeds the infective material into the lymphatics. The first appearance of the bubo is heralded by a small somewhat tender swelling in the inguinal region. The swelling increases in size, the pain becomes more intense and the skin over the glands is tense, red, edematous and excruciatingly tender. The glands are very hard at first but after a time necrosis begins and suppuration which is frequently followed by rupture through the skin ensues. Thick, creamy, greenish pus is found on incision of the mass. After the glands have softened the pain is relieved and incision and drainage is soon followed by rapid granulation. The gonococcus is not found in the tissue and the inflammation, in the majority of cases, is due to absorption of toxins rather than the presence of the specific organism. Usually the patient has an acute gonorrhea when he presents himself and the diagnosis is self-evident but a careful rectal examination should always be made to rule out the prostate and seminal vesicles as possible foci of infection.

The treatment is the essence of simplicity: The patient is put at rest and heat, is applied in the form of hot wet dressings, hot baths and hot-water bottles. If absorption is going to take place the heat will hurry it along and if the glands are going to suppurate the heat will localize the pus. If the glands become soft and fluctu-

* Submitted for publication December 9, 1929.

ant with this treatment, incise and drain, do not wait for rupture.

The so-called "iodine compress" is very useful in the early stages of a bubo, and will either abort its progress or hasten it on to resolution. The iodine compress is as follows: Paint the affected area with tincture of iodine, place over this a gauze pad saturated with glycerine, then cover this with a piece of oil silk or gutta percha and hold in place by a spica bandage. This compress can be changed daily.

Perhaps the next most common bubo is the satellite bubo of chancre. The inguinal glands in syphilis appear shortly after the appearance of the chancre. The glands insinuate themselves in a slow painless fashion and become enlarged and firm. Contrary to general opinion the glands are quite tender and painful when they have attained a moderately large size.

The presence of the chancre, the history of exposure, the Wassermann reaction, the clinical appearance of the genital lesion and the demonstration of the spirochetes in the penile sore make the diagnosis. The microorganism may also be found in the bubo in many cases with proper staining and occasionally can be found on dark-field examination of material aspirated from the swollen gland. Only rarely do the buboes rupture through the skin, and with the institution of proper antiluetic treatment they soon subside and melt away: The gumma of tertiary syphilis is also a common offender. This lesion will frequently rupture through the skin and present a sloughing, necrotic cavity which heals slowly if at all. The dark-field is usually negative but the history and the Wassermann reaction should help in making the diagnosis.

The chancroid or soft chancre, as it is frequently called, is most common among the negroes. The primary sore is usually on the penis. This appears in twenty-four to forty-eight hours after exposure and is caused by the streptobacillus described by Ducrey. The ulcerations are ragged and undermined and the floor of

the ulcer is usually covered with necrotic material which soon becomes secondarily infected. Almost always the inguinal lymph glands are involved. They become greatly swollen and tender and occasionally they rupture through the skin but more often incision reveals a quantity of thin purulent material. The glands are matted together and the process advances through the lymphatics to the whole chain. Pain is the outstanding symptom and appears early, becoming progressively worse. Healing takes place with extensive scar formation. The disease is autoinoculative and this serves as an aid in the differential diagnosis. If a small area of healthy skin on the thigh is vaccinated with a little of the material from the lesion, the appearance of a pustule in twenty-four to forty-eight hours indicates that the original lesion is a chancroid.

Treatment consists in wide incision and drainage of all infected and suppurating areas, hot wet dressings of boric acid or bichloride of mercury 1:10,000, hot baths, and the application of copper sulphate or Rosenwald's solution two or three times a day (Copper sulphate and Rosenwald's solution must be applied topically and not in the form of a wet dressing). Convalescence is usually long and tedious. Often gonorrhea and chancre are complicating factors. If this be true treatment for these conditions should be started immediately. A severe balanoposthitis or a phimosis may require dorsal slit or bilateral slit.

Granuloma inguinale is not primarily a lesion of the lymph nodes. The disease usually manifests itself first on the penis or scrotum and later the lesion may appear in the groin. The glands are not involved unless secondary infection supersedes. Diagnosis is made by inspection and microscopic examination of a bit of the tissue from the base of the ulcer. Treatment with tartar emetic gives the best results.

Tuberculosis of the inguinal nodes is not a common finding but occasionally it is seen, usually associated with tuberculosis elsewhere in the body. The glands may be

enormously enlarged and present the characteristics of an ordinary intense inflammatory process. They may rupture through the skin and form chronic draining sinuses. Except in the early stages of congestion and inflammation there is very little pain although they may be tender. During the acute stage the pain may be excruciating.

Sunshine, ultraviolet light, and the usual hygienic treatment of any tuberculous lesion should be instituted. The condition may run a very protracted course and occasionally total excision is attempted with variable results.

All too often the simpler affections of

the genital regions produce an inguinal adenitis whose underlying cause may be overlooked. Pediculosis pubis frequently produces a bubo and so also may the various non-specific infections of the penis and scrotum. This should always be kept in mind and treatment of the underlying cause be instituted. Lesions on the toes, feet and leg have also produced buboes.

As a final thought we must remember that the enlarged inguinal glands may be only a part of a systemic disease and that they may be affected in Hodgkin's disease, primary and secondary malignancies, and in the various forms of so-called blood diseases.

MINOR SURGERY OF THE ANORECTAL REGION*

LOUIS J. HIRSCHMAN, M.D. F.A.C.S.

DETROIT, MICH.

WHILE it is desirable in most cases requiring any type of surgery to have the patient in a well-equipped hospital and made to rest after the operation, there are many anorectal conditions which can be surgically treated, if necessary, in office practice and the patient not be confined to bed.

Practically every case of anal fissure, hypertrophic papillitis, anal cryptitis, single polyp, external thrombotic hemorrhoids and prolapsing internal hemorrhoids of moderate size, as well as simple direct anal fistulae and small abscesses may be treated in office practice with a large degree of success.

In a few patients, even in this day of a wider dissemination of medical and surgical knowledge among the laity, there still exists an antipathy against the hospital and an inordinate fear of surgical operations and general anesthesia.

There is a class of patients which would unquestionably fall into the hands of the irregular, the charlatan and the unethical fellow who guarantees cures, if

the regular profession did not have some non-confining method of treatment which would successfully relieve the patient of many anorectal pathologic conditions without hospitalization.

It is not my purpose to discuss the treatment of all of the diseases which could be so treated nor the various methods of treatment for any single disease in a brief article of this type. Only methods which have been successful in my hands for the treatment of such anorectal conditions as can be safely treated by the average physician in office practice will be discussed.

HEMORRHOIDS, ACUTE, THROMBOTIC

Most patients suffering from thrombotic hemorrhoids, single or multiple, can be treated in office practice. With the patient in the left lateral position on the operating table a bluish or purplish mass is noted at the anal margin. Its skin covering is stretched as a rule and the patient has usually irritated it by attempting to push it into the rectum, where it did not belong.

* Submitted for publication December 4, 1929.

After cleansing the part with alcohol and painting it with 4 per cent mercuriochrome solution, the tissues underneath, above and surrounding each hemorrhoidal mass are injected with a $\frac{1}{2}$ per cent novocaine or apothesine solution. The external hemorrhoid is then grasped with a forcep and through an elliptical wound the clot or clots evacuated. Rarely is there any arterial bleeding. If so, the spurter should be ligated with fine catgut. Some anesthesine powder is applied to the wound and a pressure gauze pad firmly strapped in place with adhesive plaster. The patient should rest three or four minutes in a recumbent position after the dressing is applied and then may go home to rest the balance of the day. He reports daily to the office for dressings until healed. He is instructed to take an ounce of mineral oil every night to prevent the formation of hard stools.

HEMORRHOIDS, INTERNAL, CHRONIC, PROLAPSING

In most cases internal hemorrhoids should be removed at one time when the patient can be confined to a hospital for at least two or three days. In office practice, however, internal hemorrhoids can be removed under infiltration anesthesia, one at a time and the patient need not lose any time from his vocation.

He is asked to report to the office after having had the bowel thoroughly cleansed by the administration of a soda bicarbonate enema the preceding night followed by another in the morning. One-half hour before his appointment for operation a grain of codeine is administered by mouth. He is put in the left lateral position and the skin surface prepared as already discussed. The anesthesia of choice is a 0.5 per cent solution of novocaine or apothesine for the preliminary injection and a 0.5 per cent solution of quinine-urea hydrochloride for postoperative anesthesia. A 20 c.c. glass syringe armed with a 2 inch 20 gauge needle is filled with the solution of choice. The skin is punctured

$\frac{1}{2}$ inch behind the posterior commissure and a few drops of the anesthetic solution are immediately injected. Several cubic centimeters of the solution are then injected in a U-shaped direction on both sides of the anal canal, until the entire circumanal skin has been infiltrated from one puncture. Two or 3 c.c. are injected deep into the sphincter muscle in the posterior commissure and the needle withdrawn. Next the entire area surrounding the anus 1 inch from the external sphincter muscle is infiltrated with a 0.5 per cent solution of quinine-urea solution and five minutes allowed to elapse. At the end of this period the sphincter should be completely relaxed and the hemorrhoids prolapsed. Inasmuch as in practically all cases there are three hemorrhoidal groups present, namely: left lateral, right anterior and right posterior groups, each group must be removed at a different time. The interval is usually one week.

HEMORRHOIDS, EXTERNAL, CUTANEOUS

These consist of tags or pouches of thickened skin occasionally containing varicose veins. They usually bear a definite relation to internal hemorrhoidal tumors and really are not true hemorrhoids at all. Inasmuch as they are annoying to the patients, interfering with the proper toilet of the parts, they are often sources of annoyance and complaint. In office practice these should be removed singly. After the skin is cleansed and sterilized the selected tag should be distended with a 0.5 per cent novocaine solution and under its base a few drops of 0.5 per cent quinine-urea solution should be injected. The hemorrhoidal tag or fold should be excised level with the surrounding skin and always radial to the anal opening. The outer extremity of the wound should never be cupped or rounded, but should always taper to a point. This allows the wound edges to come together accurately and stitches are rarely necessary. Spurting vessels should be tied with small sized catgut but venous oozing is controlled

by a compression bandage. If these cutaneous tags are small it is not necessary to confine oneself to the removal of a single one. If there is no occasion for haste, it is better to remove them singly in office practice.

FISSURE AND ULCER

A fissure is a crack usually extending through the transitional membrane lining the anal canal down into the skin. If it has existed for several days the outer or skin extremity is often thrown into a thickened crescentic fold or tab designated as a sentinel pile. Fissures usually become ulcerated and are inclined to chronicity. They may occur anywhere in the anal circumference, but many are found in the posterior quadrant. They are traumatic in origin and most often result from tearing down of a posterior crypt by sneezing, coughing, straining or the passage of hard or irritating stools. They may be produced by faulty instrumentation. The sharp stinging or cutting, throbbing, spasmodic and often agonizing pain is out of all proportion to the size of the lesion and the patient demands prompt and lasting relief.

In order to overcome this sphincter spasm, the sphincter must be put to rest. Formerly it was deemed necessary to always divulse the sphincter to accomplish this. We now know that divulsion suspends sphincteric activity by forcible overstretching, tearing the sphincter fibers and oftentimes injuring the sphincteric nerves. We now know that sphincteric rest is best accomplished by putting at rest only the area of sphincter fibers involved at the site of the lesion. Occasionally sphincteric rest of a fresh fissure can be accomplished by the injection of a 1 c.c. of 2 per cent quinine-urea solution directly underneath it. After the skin is prepared a point $\frac{1}{4}$ inch outside of the external extremity of the fissure is punctured and the entire fissure raised in a wheal produced by the injection of the quinine-urea solution. A temporary fibrous splint is

produced by the action of the quinine-urea solution in the tissues and this arc of the sphincteric circumference is given temporary physiologic rest. If a sentinel pile is present it is excised at the same time and in the same manner as already described. If the injection of quinine-urea solution does not give the patient more than temporary relief, the fissure should be incised. The sphincter should be anesthetized according to the technic already described and quinine-urea solution injected in the same manner, but the infiltration should completely surround the area involved. An incision should be made through the base of the fissure and through approximately one-fourth of the thickness of the sphincter. This incision will put these sphincter fibers at rest during the healing process. The skin edges should be incised so that there will be no overhang remaining and a trench-like wound is produced. The external part of the incision should be brought out on to the skin for at least $\frac{1}{2}$ inch. Spurting vessels should be tied and a piece of rubber tissue inserted in the wound to remain for a few hours and a compression dressing applied.

PAPILLITIS AND CRYPTITIS

Annoying and often painful symptoms are caused by hypertrophied anal papillae as well as by ulceration, and infection of the anal crypts. Anal cryptitis is a very fertile source of focal infective symptoms and should always be reckoned with in every case where a focus of infection is sought.

Hypertrophic papillitis is easily recognized on digital examination. The papillae are enlarged, thickened and usually very pale in color. Often a tear at the base of a hypertrophied papilla gives rise to sphincter spasm and other symptoms usually associated with fissure or ulcer. Infected or ulcerated crypts are found at the base of or between hypertrophied papillae. They are usually sensitive to touch and through the anoscope look angry red in

color. Often pus is expressed from the mouths of the infected crypts.

Cryptitis and papillitis usually cause anal spasm. While this condition is usually associated with internal hemorrhoids, in many cases no hemorrhoids are present. The removal of papillae and draining of crypts is easily accomplished under local anesthesia. The canal is anesthetized in the same manner as has been described for the removal of internal hemorrhoids.

Each hypertrophied papilla in a given quadrant is grasped with a fine pointed hemostat and excised from without inward with fine curved sharp-pointed scissors. If a spurting vessel is encountered it is tied with No. 0 catgut. Sometimes hypertrophied papillae may be removed with a snare or excised and touched with the galvano-cautery. All diseased crypts should be made prominent by traction with a hook-shaped tractor and excised or incised as the individual crypt demands. Any overhanging edges should be trimmed away. The insertion of a small anal tampon covered with some anesthetic and germicidal ointment is of great assistance in making the patient comfortable after the operation. This is allowed to remain until after the patient's next bowel movement.

SIMPLE, DIRECT FISTULA AND SINUS

As a general rule all fistulae are best treated in the hospital. If, however, careful study by the injection of bismuth paste and stereoscopic radiography demonstrates the fistula to be of the simple direct shallow type and not undermining the sphincter it may be excised under infiltration anesthesia in the office.

A fistula not over $1\frac{1}{2}$ inches in length and not involving the sphincter muscles may be excised in the following manner: The parts are well infiltrated by novocaine or apothesine solution, care being taken to carry the injection well underneath

as well as over and around the fistulous tract. Heated bismuth paste is then injected into the external opening and will emerge promptly from the internal opening. A soft annealed silver wire probe of a small enough gauge to enter the fistulous tract without any force is passed from the external opening. The internal extremity of the probe is grasped with a fine hemostat and brought outside of the anus and the two ends twisted together. This forms a tractor upon which the fistula is threaded. The fistula is then carefully excised while threaded on this tractor. One must be careful not to injure the sphincter and if any of its fibers are incised these incisions must be made at right angles to them. All overhanging skin must be trimmed back to at least half again the width of the wound. A piece of rubber tissue is inserted as a drain. It may be necessary in order to control oozing to use gauze for pressure. These wounds should never be packed.

The presence of gauze packing tends to stimulate the growth of fibrous tissue. This often means an overgrowth of fibrous tissue and consequent distortion of the parts. Many cases of sphincteric incontinence have been caused by gauze packing preventing the severed ends of the anal sphincters from reuniting.

No cases of anal fistula should be operated upon in office practice unless the patient is kept under constant observation until the wound is completely healed. Many a properly performed fistulectomy when followed by careless, negligent or improper after-care has resulted disastrously. Meticulous after-care is of the greatest importance in all cases of anorectal surgery. It is this careful attention to details which distinguishes the higher percentage of successful results following operations performed by proctologists compared with that done by the surgeon who only occasionally treats patients suffering from anorectal disease.

TONSILLAR ELECTRO-ENUCLEATION VERSUS TONSILLAR COAGULATION*

F. PETER HERMAN, M.D.

WEST PALM BEACH, FLA.

ELECTROSURGERY is rapidly assuming its long awaited and rightful position as a valuable adjunct to medicine and surgery.

As is the case with all newly introduced agents, it has been made to run the gauntlet. In fact, electrosurgery has been subjected to more than the usual amount of bantering. It has proved to be a good advertising medium for the charlatan. It has been a good business proposition for the medical man, with the money first characteristic. These conditions will always exist. Therefore it is not the purpose of this paper to condemn individuals. It is intended that all attacks be directed toward a procedure as an entity. These attacks shall not be biased. They shall be supported by scientific proof. An endeavor will be made to thoroughly destroy an existing wrong procedure.

For years advocates of a specifically proved, pseudosurgical procedure will persist in their adulations, this support being continued despite scientific evidence to the contrary. This has been true of tonsillar coagulation.¹

It is the hope that the thoughts here given will be granted consideration. Having been considered, that they will conclusively prove the error of tonsillar coagulation, as compared with any form of enucleation; this being particularly true of electro-enucleation.

Tonsillar coagulation means the application of a damped bipolar high-frequency current to the tonsil.² This is accomplished by thrusting a suitable electrode into the tonsillar tissue. (Figs. 1, 2.) This electrode usually consists of a slightly curved sewing needle, held in an appropriate handle. It is the active electrode.³ The disbursing electrode is usually applied

through the close application of a large block-tin applicator. (Fig. 2.) This is applied to any convenient part of the body, usually the back. The complete technique consists of many thrusts by the active electrode into different parts of the tonsil. The current is applied by pressure on a footswitch at the completion of each thrust. In this way the desired, supposedly complete, coagulation of the tonsillar surface has been effected. Only one tonsil, as a rule, is treated at a time. Usually eight days are allowed to elapse before the other tonsil is so treated. This procedure is continued over more or less time, sometimes several months, until the tonsils have apparently disappeared.

As a result of coagulation, the tonsil in all instances is greatly reduced in size, even from the time of the first current application. This reduction in size is due to dehydration and tissue necrosis. It is possible to cause an apparent disappearance of the whole tonsil with but one application of this coagulating current. In these instances, however, great pain and marked dangerous edema in the surrounding soft parts result. Such heroic treatment causes severe subsequent sloughing and bleeding. This condition is not a necessary sequence. One adept in the use of the current and technique will not be thus embarrassed.

The claims made for tonsillar coagulation are many. The more important ones will be given. There is said to be an uninterrupted social or business life. It is said to be a painless and bloodless operation. Further that there is an immediate cessation of all local and systemic symptoms, this cessation being accompanied by a rapid return of the body to normal physiological functions, these functions having

* Read before the Palm Beach Academy of Med., Oct. 26, 1928, and Dade Co. Med. Soc., Miami, Jan. 2, 1929.

been previously impaired by absorption from the focus of infection.

A true fact, regardless of the ability of

FIG. 1. A. Active electrode in process of coagulating tonsillar surface. White spots showing previous applications of coagulating current having been thus applied.

FIG. 1. B. Tonsillar fossa showing buried tonsillar tissue. (a) Superior pole; (b) a small piece of central lobe; (c) inferior pole.

the operator, is that a high frequency current is no selector of tissue, the directional forces being toward the discharging electrode (Figs. 2 and 3). It is therefore impossible to gauge the depth or breadth of coagulation when the current is used, as described in tonsillar coagulation. The

predominant idea of the operator is to cause no destruction to vital tissues. The realization of this idea, without leaving portions of tonsillar tissue, is an impossibility. If the process is carried far enough to cause the destruction of the entire tonsil, there will result a necrosis and edema of vital parts adjacent thereto. Great pain and bleeding will subsequently follow. This is particularly true of the superior pole of the tonsil. In the great majority of instances this portion reposes high up in the soft parts. It is completely surrounded by soft, vital tissues, excepting for its base. To completely necrose this submerged part must result in the formation of fibrous infarcts, in which more or less non-tonsillar tissue has been deprived of nourishment, causing its death. Irreparable damage has thus been done, this damage having been death to vital structures with subsequent malformations (Fig. 4), accompanied by great pain and danger

FIG. 1. C. A clean fossa. (p) Retained plica triangularis. (The writer in all instances attempts to retain this important anatomical structure. It is believed that its removal accounts for complaint of dry throats.)

to life. Through the exercising of great care, however, the usual end result is the complete detachment of the superior pole from the central lobe. The ever-protecting mucous membrane hurries its repair, thus quickly covering the denuded

base of this detached portion, this rapid repair undoubtedly being due to the stimulating effect of the current.

FIG. 2. Application of large discharging electrode to back, and active electrode thrust into tonsils. Directional forces of current are shown toward, or away from, tonsil into vital underlying tissues.

FIG. 3. Method of demonstrating double active electrode principle, showing directional forces. T, terminals of high frequency current. C, uninsulated portion of equal-sized electrodes suspended in egg albumen. E, Coagulated portion. This demonstration is only possible when current is applied gradually from zero to predetermined point for condition to be met. With any other application of current, it is impossible to prevent one or the other electrode from assuming rôle of active electrode. This procedure is accomplished by use of rheostatic foot switch, introduced by writer.

The result in a very short time following this separation is a complete smooth

clean covering of mucous membrane. This covering constitutes an absolute blind for the thus submerged tonsillar tissue.

FIG. 4. Postoperative mutilation; anterior pillars and uvula have been removed. Posterior pillars have become attached to posterior wall of naso and oropharynx, resulting in partial occlusion of normal opening. (This occlusion is often complete.)

A like burying is of course possible, and is actually the case in many instances, in other parts of the fossa. (Fig. 1. B.)

FIG. 5. Bipolar, electro-enucleating tonsillotome being applied to tonsil. Snare is active electrode, seizing forceps is discharging element.

The length of time before the buried focus in the throat will be manifested systemically is problematical. The factors determining it are: the size of the submerged piece of tissue, the size and virulence of the colonies of organisms contained therein, plus their ability to withstand local extermination, and to send out vanguards to the distant systemic points.

Local and systemic symptoms will subside, following any form of tonsillotomy, granting that this organ has been

FIG. 6. Tonsil has been engaged, snare drawn taut. Seizing forceps have been closed. Current may now be applied. Carriage to be drawn backward simultaneously, thus severing tonsil at its base. Proportional current properties being 88 per cent cutting and 12 per cent coagulating. This proportion being maintained for various sized masses, by varying time element that current is held in contact.

the provocative cause thereof. The cessation of the systemic symptoms is the result of the respite granted the phagocytic

FIG. 7. Tonsil has been engaged in open snare. In this instance, snare has retained its position as active electrode. Discharging electrode is separate seizing forceps (Fig. 8).

forces. This respite is due to the partial reduction in the number of the invading organisms; and to more or less destruction of their primary breeding place, the tonsil. Thus this temporary cessation of hostilities at the primary source enables the protective forces to focus their attention on the more distant secondary systemic foci. In those individuals still retaining a fair amount of general resistance these secondary foci are oft-times completely

obliterated. More often, however, they are but held in abeyance. The normal physiological activities are, for the imme-

diate time at least, allowed to function unhampered. In this way, a normal standard is approached.

It is well-known when an individual has sought relief from systemic manifestations of a primary focus of infection, the incomplete removal of this focus or the formation of a new one is early recognized by the return of these secondary conditions. They are usually in a more aggravated

form, and increased in dissemination, the end-result being a complete breaking down of the physiological entity. This complete

cessation of normal function oft-times is hastened by the ease of invasion of an epidemic organism, the protective powers of the body being unable to cope with this new menace, because of the existing endemic situation.

Rhoads and Dick⁵ have presented what seems to me an excellent treatise on this particular subject. I am herein presuming to quote *verbatim* their comments and conclusions:

COMMENT

The most frequent object in removing tonsils is to rid the body of tissue harboring bacteria capable of producing disease in other parts of the body.

Yet it is shown by this work that tonsillectomy as usually done, even by specialists of established reputation, fails to accomplish this end in 73 per cent of cases because of incomplete removal of infected tonsillar tissue.

There is even some indication that in many instances the condition resulting from incomplete tonsillectomy is worse than that existing before operation.

CONCLUSIONS

Pieces of tonsillar tissue of appreciable size were found in the throats of 73 per cent of persons who had undergone tonsillectomy.

That these "tonsil stumps" have considerable clinical significance is shown by the fact that in the fairly large series in which cultures were taken the "stumps" harbored more pathogenic bacteria per gram than tonsils removed for the first time. Also there are clinical cases in which patients with systemic diseases attributable to foci of infection failed to improve after their original tonsillectomy but improved strikingly after removal of the pieces of tonsillar tissue remaining from the first operation.

The complete removal of all tonsillar tissue is necessary when the operation of tonsillectomy is undertaken.

With these most fearsome possibilities ever present, why should tonsillar coagulation continue to exist as a procedure? To further nullify its right to continued use, is the existence of a method, or procedure, which does all that may have

been claimed for tonsillar coagulation, plus the eradication of its now known dire possibilities.

FIG. 11. Sinus tonsillaris, after removal of tonsil (right). The anterior pillar is held aside to show cleanliness of removal. It also shows total lack of undue traumatization of vital structure.

Tonsillar electro-enucleation, as implied, removes the tonsil *in toto*, immediately. A full descriptive technique will not be given here, this having been done on several previous occasions.^{1,4} The results, however, of tonsillar electro-enucleation are:

1. The tonsils are removed in their entirety with one operation. (Figs. 5-10.)

2. The operative and postoperative results are bloodless. This renders the visibility of the operative field excellent, thus preventing the possibility of failure to remove all affected tissue. It also thus safeguards all vital structures. (Fig. 1c.)

3. There is a minimum of traumatization of tissue, owing to the ease of manipulation, and the total lack of the necessity of suturing. This reduces post-operative infection to a minimum. (Fig. 11.)

4. The normal instantaneous coagulation of the lumen of the severed vessels renders nil the possibilities of systemic involvement due to metastasis. This fact, especially in the case of malignancy, is a crowning attribute.

5. There is a stimulating effect to the underlying tissues affected by the current, which hastens repair.

6. The psychological impressions, which are always favorable, are not confined to the patients or their parents, but are manifested in the confidence of the operator.

In closing, it is the earnest hope of the

writer that any remarks in this paper will not be so misconstrued as to imply other than a sincere desire to protect, primarily, our patients; secondarily, to prevent us, of the profession, from being unwittingly enmeshed.

OFFICE TREATMENT OF HEMATOMA*

VINCENT HURLEY, F.R.C.S. (ENG.)

NEW YORK

THE major injuries associated with blood effusion, e. g., hemothorax, perirenal hematoma, and hemarthrosis of the large joints, obviously do not fall within the limits of the title of this paper, which deals with the lesser hematomas of ambulatory patients.

A hematoma, in reality a subcutaneous wound, is a collection of extravasated blood, limited in its extent by the character and resistance of the surrounding structures. In actual practice the term is restricted to blood extravasations which are definitely circumscribed and tend to be spherical in shape. Apart from hemophilia, scurvy, the purpuras and the leucemias, the origin of a hematoma is invariably traumatic.

Section of a hematoma a few days old usually shows a collection of blood-clot with a soft, often fluid, center made up of blood serum. The periphery is firm and organization is taking place there. If the

hematoma is located near the skin surface, there will be a series of color changes at first dark blue, then reddish-brown, greenish-yellow, and finally a dirty yellow. The duration of the staining is variable but eventually there is complete return to normal. The clot may terminate in complete absorption or in a small mass of fibrous tissue; rarely suppuration may set in and the course will then be that of a subcutaneous abscess. Still more rare is the formation of a blood cyst with well-formed fibrous wall and yellowish-brown fluid contents frequently containing cholesterol crystals. Ossification is infrequent but occurs insubperiosteal hematoma, and particularly following large deep hematomas of the thigh where it appears in the x-ray as a lamina external and parallel to the cortex of the femur.

Diagnosis can usually be readily made in recent cases but in the later stages doubts may arise because of heat, tender-

* Submitted for publication November 22, 1929.

ness and fluctuation or when the swelling is deeply situated complicating conditions must be excluded by the usual methods.

Judging from the comic papers, hematoma is very common in the scalp. This is far from being the case as a linear wound is the usual lesion. The classic differential diagnosis between depressed fracture of the skull and hematoma of the scalp need cause no concern as skull fracture in the absence of a scalp wound is practically unknown in adults.

In the well-known "black-eye" the effusion appears very rapidly but if firm pressure be applied immediately it may be successfully limited; however, if an hour has elapsed nothing is to be gained from such treatment; a small piece of adhesive placed along the eyebrow will, in some measure, conceal the bruise.

Hematoma of the ear occurs among boxers, wrestlers, and foot-ball players. In untreated cases it results in the unsightly "cauliflower ear." Immediate treatment should succeed in evacuating the effusion as far as possible through a short incision made in the fossa of the helix, with strict asepsis. A small sterile pad is placed over the wound and a moulded soft copper wire is applied to the fossa of the helix. The auricle is then lightly padded and firmly bandaged to the side of the head. The dressing may be removed after forty-eight hours when there is little fear of the destruction of the cartilage which results in "boxer's ear." It may be noted as a curiosity that hematoma of the auricle was so common in hospitals for the insane that it was known in England as "insane ear."

Hematoma of the nasal septum may occur following trauma and should receive the attention of the rhinologist.

Injury to the female breast not infrequently results in a hematoma which may give rise to confusion in diagnosis. Spontaneous absorption is the usual course. Hematoma of the abdominal wall may be due to trauma, rupture of the rectus muscle or bleeding from the superior or inferior epigastric vessels. The diagnosis

is seldom made in bleeding from the epigastric vessels, the hematoma being recognized usually in the course of laparotomy.

Hematoma of the thigh or calf presents no unusual features. In the case of hematoma of the shin, there may be pain for a considerable period of time due to the subperiosteal hematoma frequently referred to as "bone blister." In the perianal region the thrombotic hemorrhoid, really a subcutaneous clot, is of common occurrence and is readily evacuated under local anesthesia. The subsequent small wound heals rapidly.

Hematocele of the spermatic cord or tunica vaginalis is not uncommon. The effusion into the cord may be safely left to absorb. In the case of the commoner scrotal hematocele there may be considerable difficulty in diagnosis. For this reason when there is reasonable doubt it is safest to advise exploration of the scrotum, having first obtained permission for orchidectomy, so as to deal with the pathological condition present. This, of course, is not an office procedure.

Crushing injuries of the hand and foot sometimes cause large diffuse hematomas. In these cases it is important to exclude fracture by x-ray. Blows on the nail or squeezing injuries may cause subungual hematoma which slowly absorbs, frequently with loss of the nail. If the nail is loose it may be easily removed, with or without block anesthesia. The only possible diagnostic difficulty is the occasional masquerading of a subungual melanotic tumor in the guise of a hematoma, and consequent delay in radical treatment.

Treatment. In certain early and selected cases, incision and evacuation of the clot with subsequent application of a pressure dressing meet the indications. Notably is this the case with the auricle and the thrombotic external hemorrhoid. With these exceptions and in the absence of pus formation, intelligent neglect is probably best and under conservative measures, absorption and complete resolution may be confidently anticipated in near-

ly all cases. Judicious employment of heat, the whirlpool bath, light massage, and moderate pressure are of assistance in the removal of the serum and clot. Movement both active and passive stimulates the circulation and prevents adhesions and atrophy of muscle. Suppuration should be watched for but a word of caution is necessary. More often than not, a hot tender semifluctuating swelling following

some days after an injury and associated with mild pyrexia is found on incision to be free of infection. In other words, it is difficult to be sure of the presence of pus in a hematoma, and aspiration of pus should precede incision. A blood-cyst will in relatively recent cases be satisfactorily healed by aspiration; old-standing thick-walled cysts, however, require complete resection.

THERMAL AND CHEMICAL INJURIES*

ALFRED KARSTED, M.D.

BUTTE, MONT.

IN the treatment of thermal and chemical injuries, the doctor must have at his command the various agencies that he will have to use in treating the lesions. The first requisite is to relieve pain, combat shock and to dress the wound so that infection will not set in. For pain use hypodermic injection of morphine, for shock use stimulants and maintain heat by means of hot-water bottles.

First-aid treatment of injuries is the prime requisite of the doctor so that the course of healing will go on without interruption. Many of these cases, however, come to the office already infected. An infected wound, whether from burn or other injury, should be treated at once with the idea of relieving congestion and avoid spreading of the infection. Splinting the parts and putting the tissues at rest is the first essential. Removal of foreign bodies and the cutting-away of dead tissues will facilitate drainage.

Should there be evidences of pus formation in the deeper tissues, incision and putting in a wick moistened with tr. iodine or mercurochrome will afford further drainage. Having placed the parts at rest and given free drainage, the wound should be covered with gauze saturated with a solution of boracic acid. Be sure

to have the entire gauze covered so that the gauze will not dry.

The treatment of burns depends upon the degree of burn. The superficial burn of the epidermis which has produced the formation of serum is best treated by incising the membrane and allowing the serum to escape. If the area burnt is not too large, the raised epidermis can be cut away entirely, leaving the denuded area to be treated with moist dressings of boracic acid or a 2.5 per cent aqueous solution of tannic acid.

Should there be an extensive burn apply either boric acid or compresses saturated with 2.5 per cent freshly prepared aqueous solution of tannic acid or gauze moistened with 1 per cent or 2 per cent picric acid solution and apply bandage. This will be sufficient protection for transference of the patient to either home or hospital for further treatment by any of the well-known methods. If the burn is extensive, skin grafting should be done early. If performed early before much cicatricial tissue has formed, the graft will be more apt to adhere.

Deep electric burns are very tenacious and resistant to treatment. Avoidance of infection, cutting away sloughs as nature loosens up the areas, application of nitrate

* Submitted for publication November 25, 1929.

of silver here and there and the boric ointment or zinc oxide ointment will stimulate the healing.

In frost bite initial treatment is the most important point. Avoid putting the parts in hot water at first, but attempt to bring back the circulation gradually. If the skin is livid and not yet gangrenous treat the parts by friction with snow or rubbing with towels soaked in iced water. Then as the skin becomes warmer and congestion disappears dry friction should be used and the parts wrapped in cotton.

Should there be gangrene of any of the parts it is a good rule to wait for a definite line of demarcation. Do not be too hasty to amputate.

Chilblain is a secondary effect of cold. Rub the parts daily with alcohol and apply friction with a coarse towel. For hyperemia

of the skin use zinc-oxide ointment to which a small quantity of carbolic acid or menthol has been added to relieve the itching.

In handling cases resulting from chemical burns, such as carbolic or nitric acid, the resulting necrotic area must be dressed either with boric powder or a solution of boric acid. If the gangrene is not deep the dead skin can be cut away and the underlying parts will in time slough away. Should gangrene be present in parts of fingers or toes one must again wait for a definite line of demarcation before amputating.

Roentgen-ray and radium burns are most difficult to manage, and heal slowly. After the ulcerating area has healed skin grafting in the shape of thick flap grafts have been most successful and resulted in prompt healing.

SURGICAL CONDITIONS OF THE EAR*

SAMUEL J. KOPETZKY, M.D., F.A.C.S.

NEW YORK

IN otology, as in the practice of any other surgical specialty, there are several pathological conditions which lend themselves safely to surgical treatment in the office. Such surgery, of course, is understood to be the performance of a minor operative procedure which does not in any way interfere with the patient's return to his home soon after. Anything that might possibly arise to necessitate confinement to bed contraindicates the performance of surgery in the office.

Ordinarily, the performance of a myringotomy, the removal of an aural polyp or granuloma, the removal of a necrotic ossicle, the incision of an abscess in the soft parts and the removal of cysts of the auricle can safely be done in the office and the patient sent home soon afterward. In each of these procedures certain precautions must be observed; and contrain-

dications exist at times which preclude the use of surgery in the physician's office. It is not the purpose of this paper to set forth the indications for operation, but merely to formulate a set of didactic rules for the contemplated procedure.

A myringotomy is usually more aptly performed, and the incision more correctly placed, in children above the age of three years and in adults who are extremely nervous, when the patient is given a general anesthetic. In children the use of ethyl chloride inhalation, administered so that an analgesia rather than an anesthesia is produced, does not in any way interfere with the patient's return to his home. Adults who require an anesthetic are best sent to a hospital where they can stay over night until the effects of the narcosis completely disappear.

As a rule, however, no anesthetic what-

* Submitted for publication December 3, 1929.

soever is needed. Children are mummified and the head held tightly by an assistant during the surgical procedure. Adults are told that an incision will be made in the drum which will cause a certain amount of pain, but that this pain will be no more severe than that which the disease itself is causing them. Some otologists employ a mixture of cocaine and phenol as a local anesthetic applied to the drum.

The myringotomy itself should always be performed in such a way that the knife at no time impinges on the inner tympanic wall, for injury to the latter exposes the labyrinth to infection. Strict surgical asepsis should be observed so as to minimize the danger of a secondary infection. In infants, especially, care must be exercised not to incise the skin of the external canal, since injury to this structure may be followed by infection and cellulitis of the soft tissues.

Aural polyps and granulomas also lend themselves to office surgery. Before operation is undertaken, however, one must be certain of the exact origin of the new growth. These conditions are usually found in the chronic otorrheas, both with and without bone necrosis. They are a result, either of an exuberant connective-tissue proliferation following an irritant or of the confluence of the connective-tissue resorption foci in the bony tympanic walls which indicate the area of sequestering bone. The former type is found in chronic purulent otitis media due to suppuration of the tympanic mucosa. The lesion usually springs from the inner surface of the drum, the mouth of the Eustachian tube and, occasionally, from the promontory. The latter are found in the necrotic otitis of scarlet fever and in the chronic otorrheas of the dangerous type, including cholesteatoma and tuberculosis. They usually spring from the attic and their base is broad and formed by the connective tissue of the resorption foci in the bone. Through this connection they may be in intimate contact with the membranous labyrinth, if the bone is entirely necrotic;

or a path for the spread of infection exists preformed through the vascular channels leading from the granuloma into the bone. These are the polyps which should only be removed by a radical mastoid operation, never through the external auditory meatus. Those springing from the other sources already mentioned may safely be removed in the office.

Polyps are best removed with the cold snare. They should never be pulled out. The procedure that I follow is to remove the greatest portion of the polyp until the base and attachment are clearly discernible. I then cauterize the base at a second sitting with either silver nitrate or trichloroacetic acid. Hemorrhage following this operation is usually negligible and is easily controlled by the application of adrenalin chloride.

In this connection, we may consider also the removal of the granulations which form after a radical mastoid operation. These are the result of ingrowth of the implanted squamous epithelium over the healthy connective tissue granulations which spring from the raw bone surface and of the irritating effect of one upon the other. They are always noted at the margin between the squamous epithelium and the granulating surface. I have found that they usually disappear of themselves and rarely need to be removed. As the epithelium advances, it covers these exuberant granulations and finally covers them; and the granulations recede and shrink. If they become excessive, however, and tend to delay epidermization, they may be removed with the curette or with a small biting forceps.

The removal of polyps and granulomas is best done in the office under local anesthesia. A 1 per cent solution of novocaine containing a few drops of adrenalin is injected at the posterosuperior angle of the external auditory canal. About 2 c.c. are sufficient to anesthetize the entire middle-ear mucosa.

Rarely is one called upon to remove a necrotic ossicle. Occasionally, however,

cases of chronic suppuration with a marginal perforation are seen wherein the entire middle ear has been healed and covered by epidermis and wherein a discharge still exists although no cholesteatoma is present. In such cases an isolated necrosis of the malleus or the incus is often found to be the offender; and a removal of these necrotic structures will cause a cessation of the lesion. Where the malleus alone is involved, it can safely be removed in the office, employing the method of anesthesia just mentioned. The portion of the drum attached to the malleus is incised with longitudinal incisions placed on either side of the malleus and extended upward until the outer bony attic wall is reached. The malleus is then grasped with a Hartmann forceps or other suitable instrument and gently rotated until its articulation with the incus has been severed. The attachment of the tensor tympani muscle is cut through with a small tenotomy knife placed anterior to the long process. The severance of this muscle should be done by carrying the cutting edge of the knife first upward and then downward and outward. The malleus is then removed gently. Where it is necessary to remove the incus, also, the entire procedure had best be performed in a hospital, since the danger of disturbing the stapedio-fenestra articulation, with a resultant labyrinthitis, is too great to risk in the office.

The incision of a fluctuating abscess of the soft tissues of the auricle, canal or mastoid process can be performed in the office provided that the abscess is not the result of a suppurative mastoiditis. In the latter instance, the subperiosteal abscess is part of the suppurative mastoiditis and should be treated at the time of mastoidectomy. Other abscesses, such as those due to broken-down lymph glands, furuncles or post-erysipelatous foci of purulency, can be incised with the use of a local anesthetic, preferably ethyl chloride sprayed over the affected area.

A recurrent acute infection of a mastoid previously operated upon will often evince

itself by a bulging of the scar due to an accumulation of pus within the mastoid cavity. Where the surgeon himself performed the primary operation and has an exact record of the anatomy of the parts and the areas of endocranium exposed, in such a case of recurrence he may safely incise the protruding area in the office and evacuate the pus. Where someone else has performed the original operation, it is better to hospitalize the patient and carefully expose the mastoid wound. I have in mind one such case wherein the incision over the mastoid area was found, upon reoperation, to be placed directly over a large area of exposed cerebellar dura. Had this case been incised in the office, the incision would have penetrated the dura and entered the cerebellum.

Sebaceous cysts of the ear which are situated above the auricle and are not intimately connected therewith can be nicely dissected from their bed under local anesthesia. This can be done in the surgeon's office. An injection of 1 per cent novocaine around the area of operation completely blocks it and renders it painless during the surgical procedures.

There are certain general conditions which influence the decision of the physician as to whether or not he should perform an operation in his office. Debilitating diseases such as diabetes, tuberculosis, chronic nephritis and arteriosclerosis contraindicate office surgery. The complications that these conditions bring about in themselves warrant hospitalization for the benefit of the patient and the legal protection of the doctor. Then again, there are some highly neurasthenic and impressionable individuals who will always magnify postoperative symptoms. These people are very difficult to treat after operation in any event; and they are likely to believe that the surgeon minimized their condition at the outset by operating upon them in the office. They will always feel that had they been sent to a hospital and proper emphasis placed upon the

seriousness of their condition at the start, they would not have had the same amount of suffering. All this, as well as the patho-

logical condition itself, has a bearing on whether or not a surgical procedure should be undertaken in the office.

SEBACEOUS CYSTS*

MINOR C. LILE, M.D.

SEATTLE, WASH.

SEBACEOUS cysts are tumor masses occurring in the skin and are due to the occlusion of the ducts of sebaceous glands. They are most prone to occur on the head, face, and neck but may be found anywhere that sebaceous glands occur. They vary in size from that of a small pea to that of a walnut, and inasmuch as they arise from the skin itself the skin is not freely movable over them. They consist of a discreet sac filled with a cheese-like substance, the result of sebaceous gland secretion.

Treatment consists in complete removal by excising a small ellipse of skin over the apex and dissecting the sac out intact. If infection is present incision and later a complete and more difficult dissection may be necessary, but the whole sac must be removed or recurrence is likely. If there is any question as to whether any sac remains the cavity should be swabbed with phenol and alcohol and twenty-four hour drainage instituted.

TENDON CYSTS

The most frequent site of tendon cysts is about the wrist or over the dorsum of the hand. When present they are easily brought into relief when the tendon is put on the stretch.

They consist of very thin walled sacs of synovia-like material about the size of a small cherry and are filled with a clear straw-colored, very thick gelatinous material which can only be aspirated through a large bore needle. Though of the tendon sheath, there is no open connection with it.

Treatment. Occasional cures are secured

by putting the cyst under tension and smashing by a sudden blow of a book. Aspiration and continued pressure may relieve a few, but the injection of an irritating substance such as iodine is not advisable. The only sure method is to remove them completely, which is easily done if the sac is not ruptured in the process. Those occurring on the deep tendon of the wrist are somewhat more difficult and require more care in dissection.

PREPATELLAR BURSITIS; HOUSEMAID'S KNEE

The prepatellar bursa, situated in front of the patella, may become inflamed from acute or chronic traumatism, more often the latter and seen most frequently in persons whose work requires constant kneeling. The bursa when distended may vary in size from that of a small pullet's egg to that of half an orange and may or may not be acutely tender. It is not connected with the knee joint.

Treatment. Acute cases may sometimes be relieved by aspiration and tight adhesive strapping for a prolonged period, repeating the aspiration as indicated. If this does not suffice they should be completely removed. In chronic cases, especially those in which rice-bodies are present, removal is almost always indicated. This can be accomplished fairly easily under local anesthesia by means of an elliptical incision, removing sufficient skin for neat closure, and careful dissection to remove the sac intact. Close without drainage and apply pressure. No disability results from the absence of the bursa.

* Submitted for publication December 27, 1929.

TREATMENT OF FLAT FEET*

HOWARD H. MARKEL, M.D.

SAN FRANCISCO, CALIF.

PAIN in the feet and legs is one of the most common of ailments and one that is very distressing in its effect both mentally and physically. The proper treatment of such pain naturally presupposes the proper diagnosis of the condition causing the pain. Various conditions will cause pain in feet and legs. Flat feet must be differentiated from the following conditions: Intermittent claudication and sciatic pain caused by arthritis or low back strain. A careful history that the pain comes after walking two or three blocks and stops as soon as the patient stops for a moment or two, combined with the inability to palpate the dorsal artery of the foot is practically diagnostic of intermittent claudication. To eliminate sciatic pain from our diagnosis it is necessary to examine the back for tenderness about the sacroiliac joint, to apply the Kernig test, i.e., straight leg raising, and also the history should show that the pain really travels downward in most cases at least, instead of upward. Eliminating these two causes in the feet and legs, there are three main groups of foot disability: foot strain, weak foot, and flat foot. The flat feet are of two kinds, the flexible flat feet and the rigid flat feet.

TYPICAL SYMPTOMS OF FOOT DISABILITIES: ALL DEGREES OF DISABILITY FROM SLIGHT TO EXTREME

There is an aching in the feet and legs with a greater tendency to tire, especially upon standing or walking. This aching is usually relieved by rest and the removal of weight-bearing. It is often relieved also, by rest in bed, hence is much better in the morning, comes on again toward noon and then after a rest returns in the afternoon. It is relieved by bearing weight on the outer sides of the feet. Therefore, examination

of the heels of such patient's shoes, will often disclose their being worn. These feet are sometimes subject to excessive perspiration due to interference with the circulation, and are often cold and clammy.

Such patients are often able to walk long distances, but upon even short periods of weight-bearing in standing position, the feet ache excessively. These patients have slovenly gaits, the feet are everted and the knees bent inward. Upon examination the feet of these patients divide themselves into three groups: simple foot strain, weak feet, and flat feet. In foot strain the foot is very flexible but even upon weight-bearing there is very little eversion of the foot, although marked tenderness is produced upon pressure beneath the astragaloid scaphoid ligament. This is a rather acute condition as will be brought out in the history.

There is another group of feet, however, which I classify as weak feet in which there is marked eversion of the fore part of the foot, prominence of the scaphoid, and many times complicated by a short heel cord which does not allow the foot to be dorsiflexed beyond a right angle.

Another variety of painful feet is known as flat feet. These divide themselves into the two groups, flexible and rigid. The flexible flat feet, are relaxed and everted with the scaphoid many times flat upon the ground, entirely obliterating the longitudinal arch. There is another type of flat feet known as rigid flat feet which are stiff in this pronated position with more or less spasm of the peroneal muscles which can easily be demonstrated upon attempting to supinate the foot.

One other type of foot disability is known as anterior metatarsalgia or Morton's toe, which is a most painful disability in the fore part of the foot. There is a

* Submitted for publication December 10, 1929.

painful cramp or needle-like pain in the region of the base of the fourth toe and extending into the fourth toe. This pain is periodic and when it comes is intolerable but is relieved usually by removing the shoe, massaging and manipulating the joints of the anterior arch of the foot. Many times a callous is demonstrable on the ball of the anterior part of the foot which is a compensatory thickening of the skin, nature's attempt to keep the bone from wearing through the skin. This is more frequently girls and women than in men, although some men do have it. It may or may not be present along with a flat longitudinal arch.

ETIOLOGY OF THESE VARIOUS CONDITIONS

These foot disabilities are usually caused by inability of muscular effort to bear the weight. In most cases there is a laxness of ligaments which is very commonly overlooked, but can easily be demonstrated not only in the foot, but by hyperextending the elbows, etc. Because of this relaxation of the ligaments, strain is thrown upon the muscles, hence the pain comes from muscle strain and tire and not directly from the flat foot *per se*. A standing occupation is often the cause throwing the constant strain upon these muscles. Bad shoes are most fruitful causes of foot disability. The modern shoe manufacturer has very little regard for the proper lines of the foot in the manufacture of shoes. They make a pointed toe which has the same curve on the inside as on the outer side. Of late, shoes have been made of most inelastic leathers, such as snake and lizard skins, which cannot be stretched to relieve pressure on the toes and joints. Also the high narrow spike heels that many women wear throw practically the entire weight of the body upon the fore part of the foot and produce a very marked instability, although some of the weight is carried underneath the longitudinal arch, because the French variety of heel is

actually forward beneath the scaphoid. All these factors result in stretched ligaments. Even new facets are formed on the bones near the normal joints after long periods of time.

Osteophytes and thickened periosteum are found in the variety of rigid flat feet which is often complicated by arthritis. There is marked muscle atrophy of the unused muscles and contracture of certain of the muscles, especially the calf and peroneal muscles.

TREATMENT OF FOOT STRAIN

Slight cases only require wedging of the heels $\frac{1}{8}$ or $\frac{1}{16}$ inch on the inner sides of the heels, combined with exercises. These exercises consist of actively adducting and dorsiflexing the foot forcibly into supination position and flexing the toes and holding this position for fifteen seconds, then relaxing for a few seconds, and repeated fifteen to twenty times twice a day; also a walking exercise which consists of walking barefoot or in stocking feet on the extreme outer sides of the feet with the foot adducted and supinated as in the aforementioned exercises. The patient should take one hundred steps about the room both morning and evening. Exercises of rising on the toes, in my opinion, often are not so good because they have a tendency to shorten and contract the heel cord and calf muscles.

A pad of saddler's felt carefully shaped and beveled and strapped beneath the foot by adhesive plaster with the foot well supinated, gives immediate and wonderful relief in cases of foot strain. These should be renewed twice a week for two or three weeks and then discarded and combined with wedging and exercising.

More extreme cases require these same exercises and wedging of the heels only, not the soles, for wedging of the soles merely tips the foot over by rotating in the subastragaloid joint, and does not help the longitudinal arch. It was formerly thought necessary to fit such cases with

arch supports of metal, either molded on the Whitman or Boston models, but of late years I have used a shoe which is manufactured with rigid shanks using a strip of steel which, in my experience, very seldom breaks. This shoe, combined with a simple insole in which is a felt pad inserted in a pocket, makes a very light and efficient support so that very seldom is it necessary to fit a steel support.

Extreme degrees of flat feet are of two kinds, flexible and rigid and need entirely different treatments. Even the extremely flexible flat feet that give symptoms are best treated by strapping, padding and exercises, plus a rigid arch shoe with heels wedged on the inner sides.

The personal equation, however, has to be considered when it comes to giving exercises, as some will, and many will not, do them. The most doubtful ones are the young girls of sixteen and eighteen years, in girls' schools away from home.

Some of these flexible flat feet particularly in older people, will need rigid steel plates, combined with massage. The rigid flat foot cases are a more serious problem. Some are merely irritable and after putting into casts at rest for a few weeks in supination, followed by massage and adhesive strappings, will soon clear up. Others with marked rigidity and peroneal spasm holding the foot in extreme pronation will require ether anesthesia and severe manipulation and stretching of the peroneal tendons before the reflex spasm will let go. This to be followed with plaster casts for several weeks, massage, adhesive strappings, and an external bar caliper brace for several months. This usually results in a cure, but sometimes has to be repeated.

ANTERIOR METATARSALGIA OR MORTON'S TOE

The diagnosis of this condition is so easy that it can many times be made over the telephone from the history. Upon examination, there is an acute tenderness upon pinching of the fourth metatarsal head between the thumb and fore finger. The cause of this condition is nearly always due to high heels and the narrow-toed shoes with the flexible sole. The fifth metatarsal head which should make one of the supports of the anterior or transverse arch is elevated so that the fourth metatarsal head becomes the buttress of this arch. The lateral pressure of the shoe causes the fifth head to pinch the fourth digital nerve between these metatarsal heads. Many times a callous is seen beneath this fourth metatarsal head and short heel cords is a very frequent complication.

TREATMENT OF METATARSALGIA

A proper shoe is an absolute necessity for the relief of this painful condition. Plenty of width and not too high a heel is necessary. In women, a low Cuban or military heel is allowable. Where formerly a metal anterior arch support was always used, I now use a felt pad either glued into the shoe or fastened into an insole of a rigid arch shoe.

In a very few, and those most extreme cases, an excision of the fourth metatarsal head has been done. For men, in whom this condition is rather rare, an anterior heel devised by Robert Jones of Liverpool for use in the army, is very efficient. This consists of a strip of sole leather fastened obliquely across the sole of the shoe just behind the metatarsal heads.

MINOR PATHOLOGY OF THE VULVA*

C. JEFF MILLER, M.D., F.A.C.S.

NEW ORLEANS, LA.

THE vulva, in spite of its exposure to skin germs and its proximity to the three greatest excretory orifices of the body, the anus, the urethra and the vagina, exhibits surprisingly little pathology. Small infections heal promptly and systemic infections rarely develop from it, circumstances which can be explained only on the basis of relative immunity of the vulvar skin. On the other hand, the treatment of vulvar lesions is far from satisfactory. For one thing, the pathology is on the borderline of two specialties, gynecology and dermatology; the structures concerned are definitely gynecological, yet the diseases exhibited are frequently definitely dermatological; the result is that neither specialist assumes full responsibility for them, and treatment is often incomplete and ineffective.

In the second place, while the majority of these lesions are of a minor character, there is a tendency, and I think a very unhappy one, to treat them all as of this sort. Nothing could be further from the facts. The treatment of diseases of the external genitalia implies considerably more than a mere dabbing of superficial surfaces with one lotion or another. It implies, first of all, a most accurate and careful diagnosis before any treatment at all is instituted, and it is just here that most therapy fails. Vulvar conditions are very frequently merely a local manifestation of constitutional disease. Venereal conditions of the external genitalia have an unfortunate way of extending upward if they are not properly handled. Finally, while cancer of the vulvar structures, as Taussig points out in his latest brilliant study of the subject, is next in benignity to fundal cancer, this holds true only if our prophylactic and therapeutic measures are wisely chosen and properly applied.

And this, I would point out, is not always the case because of the very tendency I have mentioned, that of regarding all vulvar pathology as of a minor character.

The treatment of vulvitis is based primarily on a determination of its causal agent, which may be an infecting organism, usually the gonococcus, less often the colon bacillus; a constitutional condition, such as diabetes; irritation from chronic discharges high in the genital tract; infection from minor skin abrasions; ordinary lack of cleanliness; or skin diseases such as eczema, herpes, infection of the hair follicles and other skin conditions common to all integumentary regions, which possess no special local characteristics and which are more properly handled by the dermatologist.

The urethra, because of its location, is ordinarily considered as one of the vulvar structures, and it may properly be included in this discussion because gonorrheal infection is perhaps the most common cause of vulvitis and the urethra is the most common point of origin. Urethritis is seldom seen in the acute stage, and if it is, the proper treatment is absolute rest in bed, particularly during the menstrual periods, if the infection is to be prevented from extending upward. This, however, is not always practical, and, because the disease gives rise to no general symptoms, it is not always submitted to by the patient. Ambulatory treatment, therefore, becomes a matter of expediency if not of wisdom. In such cases, treatment should be strictly limited to the affected parts, and should include little more than dilatation of the lower third of the urethra with a small cystoscope, and painting of this part of the canal with mercurochrome, silver nitrate, or some similar agent in solution strong enough to kill the organisms, yet

* Submitted for publication November 30, 1929.

not strong enough to desquamate and injure the tissues. When the disease has reached the chronic stage, and the organism is intrenched in the tissues and cannot be isolated in the discharge, the mere fact of urethral involvement, especially if it is associated with involvement of the urethral and vulvovaginal glands, is so constant in gonorrhea and so unusual in other types of infection, that one might make the diagnosis merely on the history of exposure, plus the typical, flea-bitten appearance of the parts. The same type of local treatment is applicable as in the acute disease, and it must be kept up faithfully and persistently before a cure can be looked for. Isolation of the patient from the source of her infection is, of course, essential. I think it only fair, in view of the excellent results they report, to mention the treatment employed by Kidd and Simpson in their clinic at the London Hospital, urethrovesical lavage, instruction in which is given the patient herself if daily visits to the clinic are not practical. I should hesitate, however, to advocate such radical treatment by the average physician, let alone by the average patient, for I do not see how extension to the bladder and to the upper genital tract can well be avoided.

If Skene's glands are involved, the duct openings of which are evident in parous women as red areolae (in nulliparous women they can be exposed by hairpin retractors or fine silver probes) local applications are seldom efficacious, and the swiftest and surest treatment is cauterization with carbolic or preferably the electric cautery, after the duct has been slit over a probe from the urethral side. Bartholinitis sometimes responds to local treatment, but if abscess formation occurs, dissection of the entire gland is imperative in most cases. The operation is not serious in itself, but it is not an office procedure because of the danger of hemorrhage.

If the vulvitis is due to lack of cleanliness, the remedy is plain. The patient should be

instructed to pay special attention to the folds of skin about the genital orifice, and should be advised of the necessity for special care after urination and defecation. In the type of vulvitis which is caused by retention of sebaceous material and smegma about the clitoris, the adhesions about the latter structure are separated, the top of the preputial folds snipped off, and the edges united with two or three catgut sutures. This is a practical office procedure, for hemorrhage is a most unlikely complication.

An investigation of the urine should not be omitted in any case of vulvitis not due to such obvious causes as those we have mentioned, especially if pruritus is a prominent symptom. The decomposition of diabetic urine is a fairly frequent cause of this condition, and the treatment is obviously the correction of the constitutional disease.

Vulvitis may also be caused by any discharge from the cervix, vagina or rectum, and here again the treatment of the disease is the treatment of the causative condition, whether by douches, local applications, curettage, dilatation of the vagina or cervix, or the use of the cautery. The patient's word should not be taken for the existence or non-existence of a discharge. A careful local examination should be made, with microscopic study of the secretions, and the treatment instituted according to the indications. Savill in this connection calls attention to a frequent and unsuspected cause of vulvitis, the leakage of mineral paraffin preparations from the rectum, which may set up an intense vulvar irritation, though the anus and perineum are unusually unaffected. In such cases, withdrawal of the offending agent promptly clears up the condition. I would mention, too, the recent work of Greenhill and Davis on the trichomonas vaginalis, this organism having proved to be a rather frequent cause of a persistent and irritating leucorrhea, and so the cause of vulvitis.

The local treatment of vulvitis is most

often the treatment of its chief symptom, pruritus. This symptom is usually spoken of as if it were a clinical entity, but it cannot be too strongly emphasized that it is not, except in those rare cases in which a definite neurosis exists, or in which, as Taussig points out, the primary cause has been removed but the habit still persists. Scrupulous cleanliness is essential, and hot Sitz baths are helpful. Local irritations must be eliminated, proper drainage of the genital tract must be secured, constitutional conditions, chiefly diabetes, are to be corrected, highly seasoned foods and stimulants are to be avoided, and general hygienic measures are to be employed. Local measures to relieve the itching include applications of weak carbolic acid solutions, silver nitrate solutions, lead and opium compresses, or similar measures. My personal opinion is that simple carbolated vaseline or some salve containing menthol gives as good results as any of the more elaborate combinations, especially if friction from clothing or from vulvar pads is eliminated. If these measures fail, local applications of 10 per cent iodine may be tried at four or five day intervals, and short x-ray exposures may prove effective. Following the suggestion of Weiner, I have relieved several cases by repeated infiltrations with novocaine, in a solution of $\frac{1}{4}$ of 1 per cent, and others with infiltrations of normal salt solution, but unfortunately the good results are not permanent.

Vulvitis in childhood differs from the condition in adults in that it is always associated with vaginitis, and that, if the gonococcus is the cause, as it most frequently is, it can be isolated in the discharge. The youth of these patients complicates the treatment, and the persistence of the organisms in the tissues makes it tedious and trying. Moreover, this disease is highly infectious, and strict prophylactic measures are necessary in the home as well as in institutions if its spread is to be avoided. The treatment consists of full exposure of the parts, preferably in the knee chest position, and thorough

painting of the structures with acriflavine, silver nitrate, mercurochrome, or some similar agent, with due care, of course, that the solution is not too strong for the delicate tissues. Douches of the same sort are given daily when possible. Recently I have been using a solution of 10 per cent mercurochrome put up in sterile jelly, injection of which into the vagina has given me rather good results. Graves advocates treatment by hot air, other authorities believe that urotropin should be given regularly to keep the tissues bathed in a solution of formaldehyde, and still others favor the use of gonorrheal vaccines. With these I have had occasional good results in children, and they are worth a trial since, even though their effect is uneven, at least they do no harm. Unremitting cleanliness is the chief requisite, and this, together with persistence in whatever treatment is adopted, is, I believe, more a factor in the cure than the special method followed.

In short, the treatment of vulvitis of all types is little more than the detection and cure of the causative condition, plus such local measures as will add to the comfort of the patient and will relieve her of the discomfort of the pruritus, which is usually the chief symptom. Acute conditions of gonorrheal origin are best handled by absolute rest. And finally, one must never forget the possibility of cancer of the vulva, which may be overlooked. In this connection a word might be said about leucoplakic vulvitis, which may or may not go on to kraurosis, but which, according to Taussig, although benign in itself, is associated with malignancy in at least half of all cases. X-ray and radium give poor results, glandular therapy cannot be relied on, but vulvectomy is both prophylactic and curative, and no time should be wasted on the trial of superficial measures before this radical one is resorted to.

Chancre plainly demands no local treatment except cleanliness; the cure here depends upon the treatment of the constitutional syphilis. Chancroid, on the other

hand, is amenable to local measures, though healing is often a slow process because of the resistance of the deeper structures. Cauterization by carbolic or the electric cautery probably gives the best results, with the use of antiseptic powders during the healing stage. Diathermy has also been advised. If the inguinal glands are involved, however, ambulatory treatment must cease and the patient must be confined to bed.

The so-called venereal warts which appear on the perineum, the mons veneris, the labia or the mouth of the vagina, are, in non-gonococcal cases, usually due to lack of cleanliness and will disappear without treatment. This is especially true of the type which appears during pregnancy. If treatment is indicated, a strong astringent solution of lead or opium, or some antiseptic powder is usually sufficient, though sometimes they must be cut off under novocaine and the bases touched with carbolic or the cautery.

The hymen may be involved in any of the infections and inflammations we have described and the treatment is the same. A special type of vaginismus may be produced by its failure to rupture during coitus, the abrasions and infections which follow the injury in turn producing sensitive granulations. In cases of this sort, after the infection has cleared up, mechanical rupture may be done. Vaginismus may be treated in the office by graduated dilatations, if no local conditions

such as fissures, caruncles, vulvitis, etc. are found to be responsible for it. For true vaginismus psychotherapy is usually necessary.

A thick, fleshy hymen may call for incision and mechanical rupture, but other anomalies of this structure as a rule offer no bar to coitus and subsequent conception, and so demand no treatment. On the other hand, imperforate hymen associated with hematocolpos is a potentially grave condition, and I would utter a very serious warning against attempting its correction anywhere but in the operating theater, under the strictest aseptic precautions. It is the sort of pathology which illustrates perfectly the point I have endeavored to make concerning the limitations of office treatment. On the surface, nothing seems simpler than the puncture of the imperforate structure. Actually, there are few operations in gynecology with greater possibilities of a subsequent sepsis, and here, as in many other cases, judgment rather than skill must decide what can and what cannot be done within the limitations of the office.

COLLODION TREATMENT OF BOILS AND CARBUNCLES*

WALTER J. ROBBINS, M.D.

NEW BRITAIN, CONN.

A BOIL is a local staphylococcus infection in the skin. As the skin is a dense structure and the staphylococcus usually is not a very virulent organism, the result is a limited amount of necrosis and a few drops of pus. These

escape in the direction of least resistance, which is toward the surface.

If the same organism invades the loose subcutaneous areolar tissue, conditions are more favorable for the spread of infection, and there is more suppuration and

* Submitted for publication November 16, 1929.

a larger necrotic mass. In order to escape, the products of inflammation must penetrate the entire thickness of the skin, and in doing this they follow paths of diminished resistance furnished by the *arrectores pilorum* muscles, the sweat and sebaceous glands, and the hair follicles. This gives rise to the cribriform openings characteristic of carbuncle.

The difference between boils and carbuncles is size, and this depends on the physical characteristics of the tissue involved. Tissue density is not the only factor. Constitutional states, like diabetes, have their influence on the course of inflammation, but other things being equal, the more compact the tissue, the greater the resistance to extension of infection.

We can render the tissue surrounding a focus of infection more compact by making use of the contractile property of collodion.

The following technic is recommended: The collodion must be contractile, i.e. collodion *u. s. p.* Flexible collodion will not do. The skin should be shaved. If an ointment has been previously used, this must be removed. Gasoline is satisfactory for this purpose. In any case, the final cleaning of the skin should be with alcohol or ether, or preferably both. The collodion is painted in a thick circular band around and on the boil, leaving an opening where it seems to be pointing; or where it is desirable that it should discharge. It is necessary that the band be wide enough to extend beyond all inflamed tissue. It is best that the middle of the band be made thick and tapered toward the periphery and toward the central opening. The collodion is applied by about ten to twenty circular strokes with a saturated swab, so as to build up a thick layer. The completed dressing resembles a thin bunion plaster in shape. The size varies from $1\frac{1}{2}$ in. with a $\frac{1}{4}$ in. opening for a small boil to 6 or 8 in. with an opening an inch or more in diameter in a carbuncle.

As the collodion dries, certain interesting

things happen. The pain is relieved immediately, within thirty seconds, and does not recur.

Wrinkles appear in the collodion and extend out on the surrounding skin, showing that the tissue is being pulled together. A profile view shows that there is a considerable projection of tissue through the central opening. If a bunion plaster were placed on the mammary gland so that the nipple projected through the opening, it would give an idea of the appearance. When this protrusion of tissue takes place it shows that the procedure has been properly carried out. After the collodion dries it is covered by a light gauze dressing large enough so that it can be secured by adhesive plaster strips placed well outside the edge of the collodion. In twenty-four to forty-eight hours this central projection breaks down and the slough is discharged, leaving a relatively small cavity.

In the case of a carbuncle the relief of pain is not so prompt and complete, but it is always considerable. It may take a week or more for the slough to be discharged.

In either a boil or carbuncle there is generally such a marked change in a few hours as to suggest that compression of the tissue results in concentration of the contained antibodies (but this is pure speculation).

If the collodion ring becomes loose before the slough has been discharged, the loose portion may be trimmed away and the dressing reinforced by more collodion, or if necessary an entire new application may be made. This should be avoided as much as possible, as repeated applications tend to set up a superficial dermatitis. When two or more boils are close together it is better to surround the group with a single band of collodion.

If a boil is located near the edge of the lip it is not possible to surround it with the collodion circle, but in this case a half circle or horseshoe band is applied. In two of the dangerous upper lip furuncles

the infection did not extend after this procedure was adopted.

There are certain limitations to the usefulness of this method. Boils and carbuncles are usually situated on extensor surfaces where contraction of the skin will exert compression, but if the skin is loose and the contour of the part is concave, as in the axilla, contraction of the collodion will result in gathering the skin together like a purse-string ligature.

In a small series of carefully measured applications the contraction of collodion was found to be quite uniform. The average contraction was 18 per cent in one hour

and 27 per cent in four hours. The extremes were 22 per cent and 32 per cent. After four hours there was very little further contraction.

The advantages claimed are:

1. Prompt relief of pain.
2. There is no incision, consequently no infection of tissue previously uninfected.
3. The surrounding skin is protected so that the primary focus is not surrounded by a secondary crop.
4. The slough is discharged promptly and healing is accelerated.
5. It is not incompatible with other methods of treatment.

HOW TO REMOVE OCULAR FOREIGN BODIES*

ROBERT MERRIAM ROGERS, M.D., F.A.C.S.

BROOKLYN, N. Y.

THE complaint of "something in my eye" is one that each and every-one of us should appreciate, especially if at some time we have been the victim.

To know one's limitations in a particular subject is better than to "take a chance." The experience gained after treating several thousand of these cases is worth while.

After ascertaining in a brief statement, what happened, place the patient in a chair, with the head rest properly adjusted, or, lacking a head rest, place the chair so that the patient's head rests against the wall. In some cases it is better to have the patient lie on the examining table.

If there is considerable eyelid spasm, which interferes with the proper examination of the eye, instil a drop of some local anesthetic, such as holocaine 1 per cent, or butyn 2 per cent, or cocaine hydrochloride 4 per cent. (Remember that cocaine dilates the pupil and causes a drying of the corneal surface.) This is done by telling the patient to "look up," at the same time pulling the lower eyelid down with the

index finger or thumb of the left hand, by pressing on the skin at the lower edge of the orbit. Instil the anesthetic on the conjunctiva of the lower lid and not on the ball of the eye. This instillation may be repeated, if necessary, at intervals of three minutes, for three doses.

Have a beam of light focused on the eye which you are examining, from a lamp with adjustable goose neck, either attached to the wall or on a floor stand (Fig. 1), placed on the right side of the operator if right handed, and on the left, if left handed. Evert the lower eyelid in the same manner as when the drops were instilled, look at the conjunctiva and give special attention to the lacrymal puncta of the lower eyelid, as it may contain an eyelash or a piece of hair (seen frequently in barbers or after a hair cut). Note whether any of the eyelashes are turned in, rubbing the eyeball. If it is a foreign body, wipe it off with a tooth pick whose end has been wrapped with cotton. If there is a piece of hair in the puncta, remove it with a pair

* Submitted for publication November 9, 1929.

of small tissue forceps. Turned in eyelashes are to be pulled out.

To inspect the conjunctival surface of

antiseptic, such as solution of argyrol 20 per cent (freshly made) or solution of mercurochrome 1:500.

FIG. 1.

the upper eyelid, grasp the eyelashes with the index finger and thumb of the left hand, tell the patient to "look down" and turn it on a cotton wrapped toothpick, at the wrinkle in the skin, which is about $\frac{1}{4}$ in. back of the edge of the eyelid and which indicates the edge of the tarsal plate. Do not fail to inspect the conjunctiva in the retrotarsal fold which is above the edge of the tarsal plate, by pushing the lower eyelid upward and against the ball of the eye, causing the conjunctiva to come into view. If a foreign body is seen, remove it with a cotton-wrapped applicator.

Direct the patient to apply compresses of cool boric acid solution every three to four hours, for five minutes until the redness and discomfort disappears. If the foreign body has been in the eye for a day or two, there will be some excess mucus or mucopurulent secretion. If so, follow each series of compresses with some

FIG. 2.

If after a careful examination of the conjunctival surface of the eyelids and the lacrymal puncta, inspect the cornea.

Take a magnifying lens in the left hand, between the index finger and thumb, using the other fingers to hold up the upper eyelid and focus a ray of light on the cornea. Examine to see if there is a foreign body present. If one is located, instil one of the anesthetics mentioned and then try to remove the particle with a cotton-wrapped applicator held in the right hand. Direct the patient to keep both eyes open and to look at some object or point so as to keep the eyes steady. Failing to remove the object with the cotton-wrapped applicator, use a blunt eye spud, previously sterilized, and have the blade of the spud nearly parallel with the surface of the cornea. If the foreign body has gone into the eye hot, as from the exhaust of an auto, or from the friction of the tires on the pavement or from an emery wheel, it will leave a dark ring or eschar, which should be removed. This is best accomplished with a foreign body needle, trying to get under or behind it, care being taken not to perforate the cornea, by digging too deeply. The combination of blunt and sharp edged spud can be secured in a universal holder and made of rustless steel (Fig. 2).

After a foreign body has been removed from the cornea, with a cotton-tipped applicator, instruct the patient to use warm applications of boric acid solution every four hours, for five minutes. If the cornea has been badly damaged and the patient is a young person, instil 1 drop of solution atropine sulphate 1 per cent. Be sure to tell the patient that "the

drop will make the pupil large and that the vision will be blurred for a few days."

If an elderly person, with much damage to the cornea, and in whom the use of homatropine or atropine solution might cause glaucoma, it is better to prescribe solution pilocarpine hydrochloride 1 per cent, to be used every three hours, to put the iris at rest.

Treatment with the warm application, and the solutions if necessary, should be continued until all congestion of the conjunctiva has disappeared. It is good plan, unless the foreign body has been wiped off with the cotton-tipped applicator, to have the patient place about $\frac{1}{2}$ inch of ointment of yellow oxide of mercury, 1 per cent, dispensed in a tube, on the lower lid conjunctiva, after everting the lid, then close the eye and gently massage the eye-ball. The ointment should be applied before retiring.

Cocaine solution, as an anesthetic, should be avoided, especially in a person past forty years of age, because it causes dilation of the pupil and might bring on an attack of glaucoma is one susceptible to this disease.

If, after a careful examination has been made, no foreign body has been found, instil a drop of 1:500 solution of mercurochrome and wash out the excess with a small amount of boric acid solution. Then examine the cornea with a ray of light, focused with the condensing lens. A red spot indicates that the conjunctival or first layer of the cornea has been abraded and the treatment indicated is the same

as when a foreign body has been removed from the cornea.

The use of smoked glasses give relief from the lacrymation and photophobia caused by bright light or sunlight.

The value of placing a dressing and bandage or the use of a black patch to cover the injured eye, instead of the dark glasses, may be determined by the amount of injury of the cornea, the distance that the injured person might have to travel in inclement weather and the general mentality of the patient and the condition of his surroundings. The laborer in the foundry or the steel mill will do better if his eye is covered between treatments to prevent contamination by dirty fingers or soiled handkerchiefs.

In young children it is sometimes possible to remove foreign bodies from the upper and lower eyelids, without much difficulty, but in case the foreign body is imbedded in the cornea, it is safer to administer a general anesthetic than to risk further damage or perforation of the cornea, in attempting the removal in a nervous, frightened and uncontrollable child.

The essentials for the successful removal of foreign bodies from the human eye may be summed up as: (1) a comfortable position for the patient's head; (2) sufficient anesthesia to render the eye insensible to pain; (3) a good beam of light on the injured eye; (4) good vision in the operator's eyes; (5) the proper sterilized instruments, and a knowledge of what to do and how to do it.

SUBCUTANEOUS FOREIGN BODIES IN MINOR SURGERY*

GEORGE K. RHODES, M.D.

SAN FRANCISCO, CALIF.

A VERY considerable number of all patients who apply for emergency treatment are victims of foreign bodies. While the injury itself may not be immediately serious we find altogether too often ill-advised emergency treatment administered. Sound judgment and application of fundamental principles of surgery are most important in handling this type of practice if we are to avoid aggravating the pathology already present.

Foreign bodies may be roughly classified into: (a) foreign bodies containing sufficient mineral matter to cast an x-ray shadow, such as steel, certain types of glass, stones, etc.; (b) those foreign bodies which do not usually contain sufficient mineral matter to cast a shadow, such as splinters and vegetable matter.

A. FOREIGN BODIES IN THE SKIN AND SUBCUTANEOUS TISSUES

In general this foreign material should be removed at the earliest possible moment after its introduction into the tissues. Certain dicta might be outlined:

1. Always study the line of transit of the foreign body through the tissues and localize the foreign body with intelligent use of the x-ray and fluoroscope when possible. Accurate localization of a foreign body facilitates its removal.

2. Operative removal often demands considerable dexterity and ingenuity. The search and removal of the foreign body must be done with the very minimum of trauma, bearing in mind that operation often further disseminates the potential infection that lurks in *all* accidental wounds.

3. The approach to a localized foreign body is usually facilitated by making the exploratory incision at right angles to the long axis of the foreign body.

4. An Esmarch's bandage applied to an extremity gives a bloodless field and far better visibility in dealing with foreign bodies or infections.

5. If a foreign body is small and deeply situated and causing no loss of function, operation is inadvisable as its removal would probably do more harm than good.

6. When the tract of a thorn or splinter is subcutaneous, it is often advisable to open up the tract throughout.

7. Blind search for a suspected splinter is usually non-productive and meddlesome surgery.

8. Removal of powder burns, dirt, sand, etc. Early removal of every particle of such insoluble foreign material is imperative if we are to avoid having them covered over by epithelium. Neglect of early adequate treatment in these cases often leaves permanent areas of discoloration in the skin similar to tattoo marks. Powder grains are so soft and numerous that it is hopeless to pick them out one by one. A thorough scrubbing (under a general anesthetic) with a stiff brush until every trace of the powder and dirt is scraped away is probably the best assurance of a satisfactory cosmetic result.

9. Foreign bodies which remain in the tissues by intent or oversight become encysted in inflammatory reactive processes, i.e., scar tissue. These encapsulated foreign bodies may at any time be the seat of an inflammatory focus which eventually leads to their removal. In other instances the foreign body implantation is associated with pyogenic infection. In the latter instance there is a resulting sinus which closes only when the foreign body is extruded spontaneously or removed.

10. A satisfactory postoperative treatment of these wounds would be that

*Submitted for publication December 7, 1929.

applicable to infected wounds in general until they are proved otherwise. Accordingly it would seem rational therapy to order rest, immobilization, sterile compresses, etc. For practical purposes an alcohol and glycerine compress affords an excellent dressing for these wounds.

11. These wounds are often in the nature of puncture wounds and hence are potential seats for anerobic cultures. Therefore we always consider and anticipate the possibility of gas or tetanus infection in each individual case. In such instances the prophylactic serum is always indicated.

STRICTURE OF THE URETHRA*

CARL RUSCHE, M.D.

HOLLYWOOD, CALIF.

TRUE stricture of the urethra is a cicatrix of the urethral wall left there by some injury or inflammation, and manifesting a constant tendency to contract, and thus to diminish the lumen of the urethra. This tendency to contraction, which is always manifested in a greater or less degree, is doubtless caused by the irritation incident to micturition; the impact of the stream against the barrier, for the deepest stricture, the one which most obstructs the flow of the urine, is almost always the tightest and if the stricture is kept dilated so as to afford little or no obstruction, the tendency to recontraction is slight.

Stricture occurs in the female as well as in the male urethra. But this lesion in the female is much less common, and manifests no distinguishing peculiarities.

Several classifications of strictures have been offered, but one I like best is to class them as inflammatory, traumatic and inflammatory strictures which have been operated and thereby have had true scar tissue added to them. About 90 per cent of all strictures of the urethra are due to inflammatory causes; 10 per cent are of traumatic origin. Inflammatory strictures are usually multiple, the deepest being always the narrowest. Sixty per cent of all gonorrheal strictures occur in the deep urethra. We find that 64 per cent of all

strictures of the male urethra occur in this portion of the canal.

The formation of inflammatory stricture is of long duration and is an interesting process. The patient contracts the gonorrhea which becomes chronic. After a number of relapses from a chronic to the subacute stage, the tissues become accustomed to the presence and growth of the gonococcus, that they react to its presence only by the formation of a round-celled infiltration of the urethral wall. As the round-celled infiltration progresses the urethral wall becomes thickened, loses its elasticity, the canal is narrowed, and we have the formation of a mass which has been given the name of stricture. In the majority of these cases the mass is palpable. As this process becomes older, connective tissue cells appear in the older portions and the mass undergoes organization, that is, it becomes converted into fibrous connective tissue. This has the nature of all newly formed fibrous tissue and as it reaches maturity it shrinks. This shrinking causes permanent loss of elasticity in the walls of the canal and partial or total obliteration of the canal itself. The thickening in the urethra is not entirely due to organized tissue, but to the completely and partially organized tissue, to which is added an area of greater or less extent of inflammatory exudate.

* Submitted for publication December 7, 1929.

When we study traumatic stricture we find an entirely different process. Here we have tissue loss in the urethral wall. We have the space filled first, with blood clot, then with an exudate which becomes organized into fibrous tissue which shrinks. In this way it distorts and obliterates the canal. In this case, however, there is no thickening of the tissues. A scar which binds two torn tissues together is never as thick as the tissue it joins. In the urethra where scar tissue replaces lost portions, the wall is thin instead of thickened. Only occasionally is there an area of chronic inflammation surrounding the lesion, so that in the majority of cases traumatic stricture is not palpable. Those cases which are palpable belong to a class of inflammatory strictures which have been operated on and we have the combination of inflammatory and traumatic stricture.

If we compare sections made from inflammatory stricture and traumatic stricture under the microscope we find they are alike, with the exception that in the tissues of inflammatory stricture are found small foci or islands of lymphocytes. These are more numerous in the newer tissue and finally entirely disappear from the old tissue. Microscopically these tissues are said to be identical, clinically, inflammatory stricture and traumatic stricture differ very much. This difference not being in the symptoms they produce or the length of time which they require for their formation, but in the fact that one permits of cure by dilatation while the other does not.

Dilatation is the accepted method of treatment of urethral stricture today. But indulged in carelessly it has fallen into disuse since it only adds to our troubles. Torn tissues always heal by the addition of scar. Dilatation can be performed in two ways, either by temporary or continuous pressure. The temporary method, that is the passage of a bougie or sound which is allowed to remain for a few seconds to a few minutes, is applicable to a stricture of large caliber. The continuous method,

where the bougie is allowed to remain for a number of hours or days, is suited to use in very narrow strictures of the deep urethra.

If a case comes to us with a dribbling or a retention and we are able to pass a filiform bougie through the stricture, this bougie should not be removed but should be fastened in such a manner that it can neither come out of the urethra nor pass into the bladder. If the bougie has apparently gone through the stricture and we are uncertain that it has followed the urethra, a rotation of the instrument, provided the proximal end of the bougie is in the urethra, will give the patient a sensation of urination and we are then certain that the bougie is within the urethra. At the end of twenty-four hours, or at the most forty-eight hours, we should be able to pass another bougie beside the first, and within the next day we should be able to pass a third. These can be allowed to remain several days longer, at which time we should be able to pass larger bougies without trouble.

In treating all strictures of the urethra one cannot tell just what portion of the inflammatory urethral obstruction is caused by organized tissue, cellular infiltration, or inflammatory exudate. We must add to our mechanical treatments those methods which seem best to relieve inflammatory conditions. Hot applications are the best for the relief of inflammation, and they are particularly valuable in the inflammations in and about the pelvis. This is true both of the female and male patient. We, therefore, add to our mechanical treatment, hot sitz baths, two per day. After enough absorption has taken place in the urethra so that a No. 10 F. or 12 F. bougie can be passed without difficulty the patient may be treated by temporary dilatation, that is by the passage of a sound or bougie every seven days. The sitz bath, however, should be kept up for three or four weeks. By this method we are able to pass a number 10 F. bougie in about a week, and in ten to fourteen days the patient

can be allowed to return to his ordinary vocation.

This method of treatment as described is applicable to inflammatory stricture because the newly formed fibrous tissue of inflammatory origin will absorb or become thinned down and stretched out to give the urethra its full caliber. Whether this is due to absorption and stretching a fibrous tissue, or to the absorption of the round-celled infiltration and inflammatory exudate in the mass, I am unable to say. This same treatment if applied to traumatic stricture is practically without results. The fibrous tissue of true scar tissue does not admit of absorption or of stretching so as to restore the caliber of the canal.

Attempts at stretching traumatic stricture have proved absolutely futile. I am

of the opinion that practically all traumatic strictures must be operated upon, and that the more quickly we give our patient this advice, the more quickly we have him on his way to recovery.

In strictures of the third class, that is, those inflammatory strictures which have been operated upon and which have not received the proper after-care but have been allowed to recontract, the proposition is somewhat different. Here we have an inflammatory tissue which we can absorb and scar tissue which we cannot remove by mechanical means. We have, however, no way of knowing the proportion in which these two conditions exist, therefore, we are justified in these cases in attempting a cure by dilatation, which we may have to lay aside after a few weeks and advise operation.

ELECTROSURGICAL GYNECOLOGICAL OFFICE PROCEDURES*

GRANT E. WARD, M.D., F.A.C.S.

BALTIMORE, MD.

ELECTROSURGERY, the incision, removal, or destruction of tissue by means of a high frequency electric current has simplified and rendered more efficient many surgical procedures. This is true in minor and major general surgery and gynecology.

Many gynecological patients require minor operations, so little incapacitating that they are reticent to entering a hospital. Before the advent of electrosurgery, hospitalization was practically a necessity because of the technical difficulties encountered in handling bleeding incisions without an assistant and hemostats. Many patients object to hospitalization for such so-called minor conditions, others being unable to leave their home or vocational duties.

Electrosurgery has made it possible to perform many of these minor gynecological operations in the office as there is little or no bleeding; the operations are technically easier; they are done under local anesthesia; healing is prompt and painless with soft pliable scars; and small malignant or potentially malignant lesions are removed completely with less danger of metastasis.

1. *Urethral Caruncle and Redundant Urethral Mucosa.* True caruncle is not as common as usually supposed. The marked tenderness of urethral caruncle is so constant as to be almost pathognomonic of the disease. Redundant mucosa is practically painless and, being more common than caruncle, is frequently mistaken for it.

* Submitted for publication December 18, 1929.

In treating either condition a local injection of 1 per cent or 2 per cent novocaine is first made inclosing a wide margin beyond the disease, frequently requiring injection all way around the urethral orifice. The caruncle is excised with a strong cutting-coagulating current. Healing is prompt after the film of destroyed tissue comes away in about a week. There is usually little pain.

Redundant mucosa is quickly destroyed by applying the monoterminal heating current directly to the surface using a sharp needle electrode. If the tumor is very thick the needle should pierce the tissue to the necessary depth.

Corbus and O'Connor¹ describe a unique method of treatment claiming that by using their technic there is little possibility of stricturing. I have never seen stricture following the usual destruction with the current.

A thin, flat electrode, $\frac{1}{2}$ inch long and $\frac{1}{8}$ inch wide, is placed in direct contact with the mucosa. A slow, biterminal current is preferred as the entire depth of the mucosa should be destroyed. The electrode is reapplied to three equidistant portions of the lumen. No shrinking is immediately appreciable, the bulging meatus showing four grayish-white lines of desiccation with normal mucosa between. Sloughing of desiccated areas takes place in a few days, symmetrical contraction of the scar tissue literally pulling the meatus and surrounding mucosa inward. If the desiccation has been done transversely with the urethral wall no actual contraction of the lumen results.

2. *Venereal Warts.* Local anesthesia is necessary here. The warts dry up quickly under the application of a monoterminal desiccating current. Heating is prompt and without notable discomfort. When the warts are thick or piled up closely together, making a bulky dehydrated mass after treatment, they are removed with a curet, the base being

re-dried with the current. Small warts after being treated are allowed to remain until they separate spontaneously allowing healing processes to continue beneath them.

3. *Cysts.* Bartholin's glands cysts are opened with the cutting current with very little or no bleeding. After evacuation of the contents the epithelial lining is destroyed with a desiccating current and the wound allowed to granulate after the destroyed tissue has sloughed. In large cysts frequent packing with iodoform gauze is helpful in keeping the wound clean, stimulating healthy granulations.

4. *Infections in Skene's and Bartholin's glands* causing recurrent infections in the urethra and cervix are frequently obstinate to usual treatment. The glands are easily sterilized by the method of Corbus and O'Connor. A long, thin needle is inserted to the depth of the gland, the current turned on and continued until the tissues adjacent are blanched, indicating dehydration. The dehydrating current produces sufficient heat to sterilize the infection. Healing is prompt and complete.

5. *Endocervicitis.* Chronic endocervicitis is a very common gynecological condition quite resistant to the usual chemical method of treatment. The large edematous cervixes with many large cysts filled with mucopurulent material require thorough cauterization, destroying the deep-seated organisms buried in the long racimose glands. Such treatment should be thorough and extend up to the internal os. Except in a few patients where general anesthesia is contraindicated, these large edematous cystic cervixes should be treated under general anesthesia. In the more mild cases the canal and external os is cleaned up with a biterminal current under local anesthesia. The current should be of comparatively low voltage and high amperage. Too high voltage will cause the current to penetrate far out into the tissues beyond the area of anesthesia giving pain. A short thick spark will destroy the mucosa and glands deeply enough to sterilize without

¹ CORBUS, and O'CONOR, *Diathermy in the Treatment of Genito-urinary Disease*. Bruce Pub. Co., 1929.

general anesthetic. If desirable, the treatment may be done at several sittings.

6. *Polyps.* Small vaginal or cervical polyps are readily destroyed with a short, thick monoterminal current. Pedunculated ones should be grasped in a clamp and the pedicle severed with a cutting current. Very little bleeding occurs, prompt healing being the rule.

7. *Hemorrhoids.* Much has been written recently about the destruction of hemorrhoids with electrosurgical currents. Suffice it to describe here those which are most readily treated in the office. It should be noted in passing that large internal and external hemorrhoids can be dehydrated (desiccated) under local anesthesia in the office. Extensive cases should be dealt with in the hospital but there are many patients having small enlarged hemorrhoidal veins which can be relieved by electrosurgery under local anesthesia. Especially is this true with patients who cannot conveniently leave their occupation for hospitalization. Ordinarily one treatment is sufficient but more than one sitting may be necessary when several hemorrhoids exist.

One or two hemorrhoids require only

local injection about them whereas multiple ones necessitate injections around the anus and up above the internal sphincter. The sphincter muscle is then dilated, releasing the spasm, which causes the hemorrhoid. A desiccating monoterminal current of short, thick spark is preferable being applied by a suitable needle electrode. The needle is thrust into the hemorrhoid and allowed to remain until the blood is dehydrated sufficiently by clot. There is, also, a small area of whitening around the point of insertion. William L. Clark advises no further treatment but Kelly and I feel that it safeguards against possible infection by incising the vein wall for subsequent drainage. The clot may be vaccinated if desired.

Larger hemorrhoids require clamping with any suitable hemostat stagnating the blood rendering dehydration and clotting more prompt. When the clamp is removed no hemorrhage occurs.

Healing is usually complete in two to three weeks with little scarring or pain. Occasionally pain does occur being readily controlled with mild sedative suppositories or instillations of sedative solutions.

INJECTION TREATMENT OF VARICOSE VEINS*

L. H. EDMUNDS, M.D.

SEATTLE, WASH.

THAT veins could be obliterated by the injection of sclerosing solution into their lumen has been known for a long time. Many physicians have noticed this phenomenon, always with more or less fear and trepidation, in the therapeutic administration of drugs intravenously for other purposes. However, until the past few years it was thought to be unscientific, in fact foolhardy, to introduce a solution into a vein with the intent purpose of forming a thrombus. The possibility of the occurrence of a

pulmonary embolus seemed to be too great to give this a second thought as a therapeutic measure. Yet McPheeters and Rice in reviewing 53,000 cases of varicose veins treated by the injection of sclerosing solutions into their lumen found only 4 authentic cases of pulmonary embolus. These same men have shown by injecting lipiodol into varicose veins of the lower extremity and observing the direction of flow under the fluoroscope, that the flow is toward the periphery in the superficial varicose veins and not toward the

* From The Mason Clinic, Seattle, Wash. Submitted for publication December 10, 1929.

heart, as we might expect. This is due to a dilatation and incompetency of the valves of the saphenous system, and as a result the blood stagnates in the lower portion of the leg. If an embolus is formed it will travel toward the periphery and lodge in one of the branches of the vein rather than proceed through the heart to the lungs.

CONTRAINDICATIONS

As more has been learned of the injection method of treatment the contraindications, which were at first thought to be numerous, are now recognized to be few indeed. Where there is a definite etiological factor present this should be corrected first, if possible, before we can expect progress very far with the treatment of the varicosities already present. With the etiological factor removed we can then proceed with the injection, knowing that new varicosities will not be formed as soon as those present are obliterated. We believe that this method is contraindicated in definite cases of cardiorenal disease and in the aged and decrepit. A further contraindication is the presence of a superficial infection of the veins of the leg and again a history or evidence of a preceding thrombophlebitis of the veins of the deep system.

SOLUTIONS

The solutions used for producing the sclerosing effect on the vein wall have been numerous. Our experience has been limited chiefly to the sodium salicylate in 20, 30, and occasionally 40 per cent and to the invert sugar in 60 and 75 per cent strength. The sodium salicylate requires greater skill on the part of the operator and a more exacting technic, for if any of this solution is deposited extravenously it will not only cause severe burning pain to the patient but will also produce a slough of the injected tissues. It has the further disadvantage of causing a very intense cramp-like pain at the time of injection lasting from one to three minutes, which

occasionally is so severe as to cause the patient to cry out in agony. However, the salicylate is extremely effective in obliterating the vein and superior to the invert sugar in this respect. On the other hand the invert sugar will not produce a slough if only a few drops are deposited extravenously but will cause a periphlebitis which, while painful, is not alarming. It generally causes a mild cramp at the time of injection, but this is not to be compared with the agonizing cramp from the salicylate. However, the invert sugar solution will sometimes have to be used two and even three times in the same vein (the large leathery type) particularly if the technic has been such that the solution has been injected into a vein partly filled with blood, thus causing a dilution and loss of effectiveness.

EQUIPMENT

The equipment necessary for the injection is simple. It consists of (1) the sclerosing solution to be used, which can be obtained in ampules; (2) a 10 c.c. Luer Lok syringe; (3) a large long needle used only for filling the syringe with the solution; (4) a fine, sharp-pointed, short-beveled needle for entering the vein; (5) rubber tube tourniquets, and (6) ordinary gauze bandage, adhesive tape, cotton and alcohol.

The aim and object of the operation is to inject the solution into the lumen of the vein in sufficient concentration to cause a definite thrombophlebitis, eventually resulting in organization and obliteration of the vein. It is also our object not to interfere with the circulation in the deep veins. Our technic has been devised with these objects in view.

The patient is asked to remove all clothing from the lower extremity. We then have him stand in the step of an ordinary examining table. This causes the varices to be distended and dilated so that they can be entered easily. Having previously filled the syringe we change the needle so that the needle we now use has none of the solution on its outside, as

this would be sufficient to cause irritation along the line of puncture. We then place a tourniquet about 3 inches below the site selected for the injection, making it tight enough to shut off only the superficial veins. Using the strictest aseptic technic we enter the vein. After we are sure that the point of the needle has entered the vein we push the point forward in the direction of the course of the vein for a distance of $\frac{1}{4}$ to $\frac{3}{8}$ inch. If this is done a slight movement on the part of the patient or a slight shakiness on the part of the operator can not cause the needle to slip out of the vein. With the needle still in the vein's lumen and before any injection is started we have the patient lie down in the horizontal position. While the operator holds the syringe with the needle in the vein an assistant carefully raises the leg to about 2 feet above the horizontal. The vein will then empty itself of blood by gravity and collapse. With the leg still in this position a second tourniquet is placed around the leg about 3 inches above the site of injection, care being taken to shut off only the superficial veins. The vein is now collapsed and segmented by tourniquets above and below. We then aspirate to make sure that the needle has not slipped out of the vein during the manipulation of the leg. If we are still within the lumen we begin injection. The injection can proceed as rapidly as is expedient, but one thing is absolutely essential, i.e. that we be sure that we are within the vein at all times during the injection. The amount injected into each vein varies with the size of that particular vein. We usually inject sufficient solution to cause a moderate distention of that vein, whether it be 5, 10, 15 or 20 c.c. When the injection has ceased we do not immediately remove the needle from the vein but allow it to remain in situ for from three to five minutes while the sclerosing solution is exerting its effect. The tourniquet can then be released and the needle withdrawn and pressure applied directly over the needle puncture. This will prevent leaking of the fluid into the tissues. We may

inject two or three veins on each leg with the sugar solution at each sitting, but it is not believed wise to inject more than two veins at one time with the salicylate.

As to the frequency of injections it is probably best to wait about ten days between treatment. This will allow time to observe the effects of the previous injection and we are then better able to judge the necessity for further injections. In less time than this we will be unable to tell what veins have been sufficiently affected by the solution to be obliterated. A good injection into a large varix will frequently obliterate most of the smaller tributary varices in this segment, thus obviating the necessity of injecting them separately.

Some operators have felt hesitant about injecting the saphenous vein high up in the thigh, contending that embolus is more apt to be dislodged in this region. In view of the before-mentioned work of McPheeters and Rice, this does not seem to be a logical contention and the saphenous vein can be injected close to the femoral opening with as much assurance of safety as elsewhere in the leg.

After a proper injection there will be slight inflammation and redness along the course of the vein. This will cause some inconvenience to the patient for two or three days but nothing more. If any of the solution is deposited extravascularly a severe periphlebitis and paraphlebitis will occur, and if much is deposited a slough will be produced. At the end of two weeks the vein can be felt as a fibrous cord running up the leg. However, organization will not be complete for from sixty to ninety days.

RECURRENCE

Many patients ask the question, "Doctor, will these come back?" We can tell these patients with a fair degree of assurance that the ones injected and obliterated will not come back. However, we must explain that the mere injection and obliteration of the veins already present will not

prevent the formation of new ones and there will be the same tendency to form new ones as there was to form the original ones. For this reason the patient should

report for observation at least once a year after he has been discharged, at which time all newly formed varices can be taken care of at one sitting.

TREATMENT OF FRACTURES OF FINGERS AND TOES*

C. R. G. FORRESTER, M.D., AND DAN R. MCLEAN, M.D.

CHICAGO

AS the anatomical characteristics of the bony structures about the toes are for all practical purposes the same as the fingers a single classification of the types can be made. From a functional as well as a cosmetic standpoint, however, the treatment of the finger fracture is more important than the toe fracture. We will write of all of the injuries as fractures of the fingers but the same treatment can be applied to like fractures of the toes.

The fingers as well as the toes consist of three phalanges with their attached and associated muscles, tendons and joints, with the exception of the thumb (analogous to great toe) which consists of only two phalanges and whose function is more highly specialized than the rest of those small structures. The most simple as well as general classification of the fractures is as follows:

1. Chipping and comminuted fractures of the spongy portion of the distal phalanx.
2. Transverse fractures of the shaft.
3. Spiral fractures of the shaft.
4. T-fractures into the joint.
5. Tearing loose of the tendon insertions.

Any of these types can be compound rather than simple.

Practically all fractures are treated in our office under local anesthesia, using the technic taught by Prof. Lorenz Boehler of Vienna. This consists of the painting of the skin over the site of fracture with iodine followed by alcohol. A sterile needle is then introduced between the fragmented bone, care being used to get this

into the hematoma produced at the time of injury. Then about 5 c.c. of 2 per cent novocaine without adrenalin are injected through this needle directly into the hematoma, which is in this way the carrying agent as well as the dispersing of the anesthetic. After a short interval of time (depending on the age of the fracture) manipulation can be carried on painlessly. In compound wounds the injection should be made on the opposite side of the compound wound and a through debridement of the wound with closure of the skin made. Fracture of the digits can also be done under a nerve-block anesthesia of the lateral nerves but we have found the direct local to be the simplest as well as the most efficacious.

Chipping and comminuted fractures of the spongy portion of the distal phalanx are usually associated with some hemorrhage under the finger nail. In order to relieve the tension and pain caused by this condition the nail is opened widely to permit of drainage (no anesthesia is used); the fragments are moulded into good position by direct pressure, and a small tongue depressor splint, from the proximal interphalangeal joint, so that it projects well over the tip of the finger, is bandaged in place. The bandage can be changed as necessary with the splint allowed to remain in place about three weeks and the patient allowed to use his finger. He may be discharged in one month.

Fractures of the middle of the shaft of the distal phalanx are associated with

* Submitted for publication December 18, 1929.

some displacement but not with the deformity due to muscle pull. These fractures can be injected with the local anesthetic, a primary reduction by manipulation and traction and a small tongue depressor splint applied on the flexor surface so that it immobilizes the distal interphalangeal joint.

In traumatic work we often come in contact with a case which has received either a direct blow, a forcible flexion or extension of the distal phalanx. These cases show an immediate droop of the distal phalanx into flexion. The x-ray will reveal a small chip fracture of the proximal end of the distal phalanx at the insertion of the extensor tendon. The end-result in these cases, in practically all instances, is permanent deformity of the distal interphalangeal joint with some loss in extension. Occasionally by moulding and counter-pressure over this area together with a palmar splint along the whole of the finger, the detached piece can be replaced. It is usually well to put a piece of hard roller bandage on the distal end of the splint and by adhesive hold the distal phalanx in shape extension as shown in Fig. 1.

The splint in this condition, however, must be allowed to remain in place about four weeks and one should not be surprised if the flexion deformity recurs on its removal. We have practically never opened up one of these cases to tack the tendinous insertion in place.

T-fractures into the joint can all be very effectively and practically reduced under local anesthesia. Small appropriate splints are used to hold them in place, keeping in mind, however, the value of early motion for restoration of function. In our practice we begin this passive motion in ten to fourteen days and replace the splint until about the seventeenth to twenty-first day. These fractures are associated with somewhat longer disabilities and as an end-result some slight impairment in motion due to intra-articular deposition of callus is likely.

Spiral and oblique fractures of the shaft,

either of the middle or proximal phalanx, are associated with deformity and shortening due to muscle pull. They are very

FIGS. 1. and 2. B, bandage. D, depressor.

difficult to hold in position after their reduction, which is always done under a local anesthesia. A glue is made of acetone and celluloid so it is of a fairly thick consistency, and by means of this we are able to attach bandage to the finger for traction. A plaster collar is put on over the wrist and in which we incorporate one strand of piano wire bent as shown in Figure 2. By means of heavy rubber bands attached to the plaster and which can be twisted to make traction, the fragments can be held in excellent position and alignment. The whole is covered with a bandage and allowed to remain in place for a period of three weeks when removed. Active and passive movements with heat and massage instituted, recovery takes place in six weeks with small functional impairment aside from the bony thickening at the site of injury.

Fractures of the proximal or base phalanx, whether treated by traction as given here, or any other method, are all held in retentive apparatus in some degree of flexion at the metacarpophalangeal joint due to the anatomical attachment of the muscles. The lumbricales are inserted at the proximal end of the middle phalanx, hence when the finger is dorsal to the midline they extend the middle phalanx on its corresponding proximal phalanx, and when the phalanx is ventral to the midline they act as flexors of it. The interossei, however, at their attachment at the proximal end of the base phalanx always act as flexors of this phalanx. Therefore any fracture distal

to the insertion of the interossei and proximal interphalangeal joint is associated with palmar angulation at the site of fracture. By dressing this type of injury in flexion we relax the interossei muscles and thus relieve our oppositive action. After anesthetizing these fractures with our local anesthetic, acutely flexing the proximal phalanx, we are often able to obtain a 100 per cent result without the

use of traction. They can then be dressed over a roll of bandage in the palm of the hand for three weeks, when they should be released and active and passive motion started. Recovery is usually complete after six weeks from date of injury.

The writers appreciate the fact that there are many important features of these cases which they have not dealt with completely in the small space allotted

SIMPLE BALANITIS*

F. S. DILLINGHAM, M.D.

LOS ANGELES, CALIF.

HAVING made the diagnosis of simple balanitis, the next step is gently to clean the surface and follow this with some mild antiseptic. One of the most dependable treatments is the constant moist dressing: A thin layer of cotton or one thickness of a gauze bandage is moistened with a mild antiseptic and placed over the glands in a smooth layer and the foreskin replaced. The dressing should be changed several times a day (i.e. at each urination). Thiersch solution,¹ or 1:4000 or 1:8000 bichloride solution are examples of well-tried remedies.

If there has been too long a delay in beginning treatments, the surface may be painted with rivanol 1:1000 or 1:2000, or

¹ Thiersch powder: 1 part Ac. salicylic

7 parts Ac. boric.

Thiersch solution: Thiersch powder 4.

Aqua 500.

mercurochrome 2 to 8 per cent followed by a constant moist dressing. After the acute infection has been cured, it is well to follow by dusting once or twice a day with zinc stearate or some bland dusting powder.

If the foreskin cannot be retracted, the glands may be cleansed by using a hand syringe with a suitable nozzle or an irrigator under low pressure and a glass tip that will enter without blocking using a mild permanganate of potassium solution, rivanol or mercurochrome solution 1:1000 or 1:2000.

If there is not a prompt response and the foreskin cannot be retracted, a circumcision should be performed, making a dorsal slit in order thoroughly to disinfect the parts and then finish the circumcision and treat the balanitis openly.

* Submitted for publication November 19, 1929.

DIRTY WOUNDS*

HORACE STIMSON, M.D.

CHICAGO, ILL.

INTRODUCTION

THIS brief and dogmatic paper is intended to show how fresh dirty wounds should be cleansed and treated in the physician's office, often distant from centers of population and limited in facilities. The writer does not pretend to add any startling improvements to an old subject but simply to emphasize certain methods and rules which have proved valuable in the writer's association and experience with a clinic treating a large number of injured people. It is not within the scope of this paper to exhaust the particular aspects of treatment in wounds of various types or to discuss the abundant literature on the subject.

PRELIMINARY CARE OF THE PATIENT

Reassure the alarmed and wounded patient, gain his confidence, make him as comfortable as possible, remove sufficient clothing to expose the wound freely and allow for proper dressings to be placed. For most wounds, make the patient lie on a dressing table, as he often faints and falls at the sight or pain of a trivial wound under treatment. If the injury is large, painful or serious, if shock, fright, hemorrhage or restlessness is present, quiet the patient with morphine (the Mulford type of tube being convenient for this purpose). Laymen should be excluded from the treatment room as they only handicap operator and patient, and create disturbance. A good nurse is invaluable. Be swift but orderly in your procedure, and take charge of the situation at once. The earlier you start treatment after injury, the better is the result and the less the danger of infection. First then, remember you are treating a whole human being, not simply an isolated wound.

PRELIMINARY CLEANSE

Green soap and warm water serve to cleanse the wounded surface and an adjacent area sufficient to allow for proper treatment and dressing fixation. The scrub must be thorough. A brief foot or hand bath of warm water mixed with green soap and lysol is effective for dirty wounds of extremities; it softens foreign matter so it can be easily removed, also green soap in itself possesses antiseptic qualities.

SHAVE

You can become skillful enough with an old fashioned razor to shave out only the extreme wound edges without inflicting pain, but also a large enough adjacent area to allow dressing fixation and to prevent wound contamination by hair and skin debris. Dry the parts with sterile gauze.

DEBRIDEMENT AND EXPLORATION

This means removal of *all* foreign matter and traumatized tissue from edges and depths of the wound. A tourniquet is seldom necessary but can be used to advantage in a finger injury where blood obscures the field and hampers identification of débris and structures. Aside from obvious dirt and hair, all traumatized or devitalized tissue such as fat and skin fragments must be removed, by extraction, curettage, excision or irrigation. Cut away and shape dirty and rough skin edges to allow neat closure. Identify all structures and layers; if necessary, enlarge the wound for proper exploration débridement and repair. Look for injured bone, vessel, nerve, tendon, muscle and sheath, and after the wound toilet restore the anatomy as nearly as possible. Débridement is essential for prevention of subsequent infection; it must be done gently, quickly and thoroughly. In puncture wounds (espe-

* Submitted for publication November 30, 1929.

cially of feet) cut away the sealed lips of the wound, curette the tract clean of all loose tissue and dirt, cauterize the tract with carbolic acid on a toothpick swab; insert a small braided silk wick. Then tetanus antitoxin will often be unnecessary, provided the wound is dressed the day of injury.

In connection with débridement, to prevent pain (with or without the preliminary morphinization) use 1 per cent or 2 per cent novocaine. Of course, in small contused wounds there is often sufficient numbing of sensation so that the wound can be treated without undue pain or necessity of novocaine. For the other and larger wounds, prepare the surrounding skin with tincture of iodine and alcohol, avoiding the fresh wound itself, then inject novocaine intradermally and subdermally *around* the wound, or use a nerve block anesthesia in an extremity (e.g. finger). The local anesthetic is thus introduced through an undamaged and surgically prepared surface instead of through the dirty wound, which may then be treated painlessly and doused with antiseptic before repair.

CONTROL OF HEMORRHAGE

If bleeding is profuse, control at once by pressure, elevation rest and morphine, by tourniquet, or clamping the "bleeders." Hemorrhage must be controlled at the latest before wound closure, as a hematoma or "wet field" invites infection and delayed or faulty healing; there is also the danger of late or secondary hemorrhage when the patient is out of your reach. Use plain catgut ties or deep skin tension sutures.

DRAINAGE

If slow oozing is expected, use a small drain (silk, silkworm gut, gutta percha or rubber-dam) placed according to the size of the wound to allow dependent drainage from the wound depths for the first thirty-six hours. We use drainage for prevention of infection only when there is delay in starting treatment (two to three hours

after injury), or in case of a wound so grossly dirty and traumatized that not all devitalized or foreign matter can be removed without too great sacrifice of tissue. Thirty-six to forty-eight hours tell the story as to whether drains can be removed and healing by first intention expected.

ANTISEPTIC AGENTS

In our experience, thorough cleansing with green soap and water, shave and débridement followed by dousing of the wound with freshly prepared tincture of iodine has given the best results, i.e. the minimum of subsequent infection as compared with the use of other measures and other antiseptics. The few cases of infection following this régime are attributable to excessive trauma and tissue devitalization, excessive dirt, or delay in initiating proper treatment. We have lost faith in the use of acriflavine, mercurochrome, hexylresorcinol and the other widely used weaker antiseptics for any but surface wounds, though we use them for superficial lacerations or abrasions where the painful iodine can be legitimately avoided. In scalp or face wounds, avoid burning the eyes or mucous membranes with strong antiseptics. With compound skull wounds (seldom treated except in hospital) we use great precautions: the whole scalp is shaved, scrubbed with green soap and water, flushed with sterile water, dried, wiped with ether, then prepared with tincture of iodine and alcohol; this procedure is simple, quick and effective. We use a solution of ether and iodoform (ether 59.15 c.c., iodoform 5.53 c.c.) in a compound skull fracture wound, drenching it freely after débridement. The dura when covered by sterile gauze is not harmed by this fluid. Phenol in puncture wounds has been mentioned before.

Dakin's solution is an excellent antiseptic for wound irrigation, when it is freshly and carefully prepared, but can not be available or suitable for most offices. Dichloramine-r in oil is excellent,

if prepared by a good pharmacist; it is stable, suitable for office use, but more applicable to the already infected and deep open wound.

REPAIR

This is mentioned, though somewhat out of the scope of the paper. After wound preparation, each damaged structure is repaired to restore anatomy and function of the part. Use absorbable and interrupted sutures in these dirty wounds which are potentially infected. In tendon or nerve repair, where strength is essential, silk or linen must be chanced and brief drainage allowed. In our clinic we are accustomed to close all wounds after the careful preparation given here; others of you may prefer to drain more often and widely, using secondary closure when infection or its danger is past. Speed, gentleness and skillful approximation of tissues add greatly to the prospect of good repair and escape from infection.

DRESSING AND AFTER-CARE

Use a soft, firm non-constricting dressing of sterile gauze, as small as possible but adequate for any expected oozing; fix with narrow adhesive strips over the gauze or bandage. Avoid collodion dressings, especially on scalp wounds, as they seal exudate and form an ideal culture media for bacteria. Elevation, immobilization, rest and warmth aid nature in preventing hemorrhage and infection, also

promote repair in the early stages of wound healing. Give a protective dose of tetanus antitoxin (1500 units) if there is any question of wound contamination with street dirt or soil, in a dirty puncture, or for severe head wounds. Initiate Pasteur treatment (e.g. the 14 dose Cumming's modification of antirabies inoculations) if there is any question of a rabid animal bite. Be sure your patient takes away medicine (as codeine or aspirin) to tide him over the first hours of discomfort. Before he leaves your office ascertain that he is prepared for comfortable transportation to his destination.

SUMMARY AND CONCLUSION

The following points are emphasized in their order of application for the treatment of fresh dirty wounds in the physician's office: Green soap and water, mechanical cleanse of the wound and its neighborhood, shave, local novocaine if indicated for a painful wound, thorough exploration and débridement, control of bleeding, antisepsis, repair, drainage, dressing and after-care. Scrupulous practice of these details is rewarded by healing *per primam* in a very large percentage of originally dirty and potentially infected wounds.

The writer in his association with Drs. C. R. G. Forrester, H. C. Lyman, and D. R. McLean is indebted to them for their example and aid in proving the efficacy of these rules of treatment.

SCALP BURNS IN WOMEN*

ROBERT T. FINDLAY, M.D.

NEW YORK

THIS article deals with a discussion of burns of the scalp, caused principally by permanent waving of the hair. Due to the present vogue of waved hair and the age-old attitude of women to

be "in style", regardless of price or personal risk, the problem of injuries received during permanent waving has become of increasing surgical importance.

This series comprises the observation of

* Submitted for publication December 21, 1929.

19 cases of burns of the scalp seen during the past year and a half, 15 of which were treated by the writer; the observation of the remaining 4 cases was confined to an examination after the burned area had entirely healed.

The burns were all in women between the ages of nineteen and fifty years, with an average of about thirty-six years. Most of them were housewives but several were otherwise occupied, as stenographers, dressmakers, a nurse, etc. These women all received their injuries in hairdressing establishments or beauty parlors and the burn occurred in all but one case during the permanent waving of the hair. The remaining patient was burned by a hot iron while having a marcel wave. The cases came from 16 different establishments. Only two shops had more than one case, one having two, the other three.

According to the patients' statements the burns were thought to be due to excessive heat in 18 cases. In 16 cases the patients informed the operator of excessive heat and pain in the scalp. It is interesting to note that in only 4 of these were the complaints heeded, that is, the apparatus was turned off immediately and the area investigated; in 2 cases the complaints were partially heeded, i.e. the heat was turned off but the area was not investigated and the heat was resumed; and in 10 cases the complaints were entirely unheeded, the heat being allowed to remain on the required length of time. In one case the felt pad under the heating unit, which is supposed to protect the scalp, was actually charred. Two patients blamed their burns on inexperienced operators. In these cases the operators were students. The permanent waving during which these burns were received was done by regular operators or hairdressers in 14 cases, by the proprietor himself in one case, by students in 3 cases and undetermined in one case. In 5 cases the burns were acknowledged by the operator at the time. In 2 cases they were partially acknowledged, that is, some mention was made of a "red spot" on the

scalp. In the remaining 11 cases, however, the burns were not acknowledged. This seems very negligent and very likely was in many cases but I believe that it is only fair to bear in mind that first and even some second degree burns are not all apparent immediately after the receipt of the burn; also that after the rather strenuous treatment which the scalp receives during any permanent wave that it would naturally be slightly hyperemic in appearance and probably more sensitive than it normally is.

In 10 cases the patients received no advice or treatment for their burns before leaving the hairdressing establishments. Eight cases were, at some time, advised or treated by the establishment, 2 of these being delayed several days, while one case was undetermined. The treatment consisted in the application of an ointment in 5 cases, oil in one, vaseline in one, collodion in one, a current of cold air in one, a shampoo in one, and advice against the use of a comb over the burned area in 3 cases. It is the opinion of the writer that there is no first-aid treatment that could be administered by the beauty parlor or by the patient which would do any good and practically all that has been done, as already described, is harmful. We will see under Treatment that any ointment or oily substance is harmful as it aids in defeating the entire principle of treatment. The opinion is, therefore, that the operators or proprietors of the hairdressing establishments should administer absolutely no treatment for the burns. It will give both the operator and the patient a false sense of security if any such treatment is carried out. Eleven of the patients did not treat themselves and 7 did, while one was undetermined. One of the 7 was treated by a nurse and the others applied ointments, vaseline and various concoctions.

Two of the cases were seen by the writer on the day the burns were received and a total of 9 were seen during the first week. The longest interval was ninety days with an average of thirteen days.

This delay, of course, made the proportion of infected cases much higher and was responsible in most cases for the resulting scar and hair loss. Eleven patients had not been under the treatment of any other physician before coming under the observation of the writer, 4 had had professional treatment before and 2 after. The number of treatments per patient by other physicians varied from 1 to 14 with an average of about 5 visits. The treatment by other physicians consisted partly in the following: The hair was clipped in only 2 cases, one at the request of the patient; in one case the doctor advised shaving over the burned area which the patient refused to have done; scabs were removed in one case; ointment prescribed in one, oil in another, boric acid in another; and in one case the patient was advised over the phone, the physician not having seen the burn. Adequate treatment of 16 of the cases was delayed; there was no delay in 2 and one was undetermined. Of the 15 cases treated by the writer, the treatment in only 2 cases was not delayed, that is, these 2 patients came for treatment on the day they received the burn. The remaining 13 were delayed. The number of days before putting themselves under the writer's care varied from none to ninety with an average of 11.6 days.

Symptoms. The patient's complaints were as follows:

1. Pain in all 19 cases.
2. Swelling in 10 cases (local).
3. Swelling of neck in 4 cases (regional adenitis was present in 4 cases, 2 anterior and 2 posterior).
4. Swelling of face in 1 case.
5. Earache in 1 case.
6. Fainting in 1 case.
7. Purulent discharge in 1 case.
8. Unsightly appearance in 1 case.

Diagnosis. We are dealing with burns of the scalp, the burning of the hair being a factor in only a few cases. The total number of burns in 18 cases was 47, one case being undetermined. The

average was 2.6 burns per patient. In 10 cases the burns were single (55 per cent of the cases) and in eight (45 per cent) the burns were multiple. This emphasizes the importance of not overlooking any burned areas, as the patient may complain of one burn and have several others in other regions of the scalp which may not at the time cause any symptoms. The reason why these burns are liable to be multiple lies in the structure of the permanent wave machine. A short description of the machine will facilitate the understanding of the occurrence of these burns and why they are often multiple.

A permanent waving machine is made up of several dozen units attached to a central source of heat. Each unit is a cylinder with a rod running through it. The hair is wound tightly around this rod and the cylinder clamped around the rod. A felt pad is placed between the scalp and the unit to protect the scalp from the heat and the waving agent. The wound hair in the cylinder is moistened by a solution known as the waving agent and then steam is introduced into the cylinder. This procedure is repeated, using a small amount of hair to each unit until the entire scalp is covered. The waving agent in a majority of cases contains ammonia. The strength and quantity of the solution, as well as the amount and degree of heat, vary with the texture of the hair and the age of the individual. All of the solutions are alkaline. That is one reason why the use of tannic acid in the treatment of scalp burns caused during permanent waving is particularly indicated as it tends to counteract the effects of the alkali as well as to treat the thermic burns.

The parietal regions were most often affected, with 15 burns; occipital, 11; frontal, 10; temporal, 2; and one case undetermined as there were no scars at the time the case was examined. A more detailed delineation to show the distribution of these burns is as follows:

| | Burns |
|----------------------------|-------|
| 1. Frontal (unspecified) | 5 |
| 2. Right frontal | 3 |
| 3. Left frontal | 1 |
| 4. Left temporal | 2 |
| 5. Parietal (unspecified) | 6 |
| 6. Right parietal | 2 |
| 7. Left parietal | 3 |
| 8. Midparietal | 4 |
| 9. Occipital (unspecified) | 7 |
| 10. Left occipital | 3 |
| 11. Mid occipital | 1 |
| 12. Undetermined | 1 |

Only one burn was first degree; 4 were first and second degree; 13 were second degree; one was second and third degree; none were third degree alone, and one was undetermined.

The size of the burns on first examination varied from $\frac{1}{8}$ inch in diameter to $1\frac{3}{4}$ inches in diameter. The average diameter was .69 inches, or nearly $\frac{3}{4}$ inch. The total area of the 47 burns was 29.1 sq. in., the average area per case being 1.61 sq. in. and the average area per burn being .61 sq. in.

Treatment. Referring to the technic used in the cases which came under the writer's care (this will be described later in detail), 6 cases had the usual technic; tannic acid was used in 3; debridement under ethyl chloride local anesthesia was done in 3, and poulticing was used in 6. The total number of treatments by the writer in his 15 cases was 88, varying from 1 to 11, with an average of 5.86 treatments. The total number of treatments in 9 cases treated by other physicians both before or after the writer's treatment was 61, varying between 1 and 14 with an average of 6.77 treatments.

Morbidity. This refers to the number of days from the day of injury until the burned areas are entirely healed and require no further treatment. The morbidity varied from seven to one hundred twenty days with an average of 35.9 days. Considering only the writer's 15 cases the average was 37.6 days.

Ten of the cases were completed and followed to determine the presence or absence of permanent defect, 3 were partially followed; one was not followed;

3 were only examined after the burns had healed, and in one case a follow-up was unnecessary (clean case).

Some disability was suffered in all cases. Those that were employed lost time from work, either because of the pain or because of their appearance. This partial disability varied from one to thirty days with an average of about thirteen days.

Infection. Fourteen cases were infected, or 73.6 per cent, and 5, or 26.4 per cent, were not. Of the 15 cases treated by the writer 11 were infected before their first visit and 4 were not. None of these 4 became infected. These were cases that had not delayed treatment too long, 2 were seen on the day the burn occurred, one the following day and the other three days later. There were no permanent defects in these 4 cases. Thus the opportunity for the ideal treatment was offered in only 4 cases.

Results. Eleven of the patients or 58.8 per cent, had a permanent defect, 4 did not have a defect; 2 would probably not and 2 were undetermined.

There were resulting scars in 13 cases, 2 would probably not be permanent; 4 cases healed without any scar; 2 were undetermined, and one would probably not have a scar. There was an area of permanent hair loss in 10 cases; none in 6; 2 were undetermined, and one would probably not have hair loss. The size of the resultant scars varied from $\frac{1}{8} \times \frac{1}{16}$ in. to $\frac{7}{8} \times \frac{3}{4}$ in. The largest measurement was $1\frac{1}{4}$ in. The average diameter was $\frac{5}{8}$ in. The total area of scars in the 11 cases was 2 sq. in. The average area was $\frac{1}{6}$ sq. in.

The scars were well distributed throughout the scalp, one in the frontal region, one temporal, 4 parietal and 5 occipital.

The detailed areas were:

| | Cases |
|----------------------------|-------|
| 1. Left frontal | 1 |
| 2. Left temporal | 1 |
| 3. Right parietal | 1 |
| 4. Left parietal | 2 |
| 5. Mid-parietal | 1 |
| 6. Occipital (unspecified) | 1 |
| 7. Left occipital | 3 |
| 8. Mid-occipital | 1 |

Miscellaneous. It was interesting to note in 2 cases, both being eight weeks after the onset of the treatment (hair shaved over burn), that the hair had grown out from this area $2\frac{1}{2}$ in. in one case and $1\frac{1}{2}$ in. in the other. In one case, a young lady of twenty-four complained that since her burn her hair was becoming progressively gray (generalized, not in the area of the burn). This was a case that had had one burn, was treated immediately, remained clean and healed without scar or hair loss. The patient suffered no pain after the first day. It is the opinion of the writer that the burn did not cause the graying of the hair, which has not been observed in any of the other cases. In only one case was the burning of the hair an important factor. This was a case in which a small portion of hair was burned with only a first degree burn of the scalp.

TREATMENT

The treatment is very simple but like many apparently insignificant conditions the common fault is conservatism. The majority of physicians who had treated these cases, prior to their coming under the observation of the writer, made light of the burns, told the patients to apply a little oil or ointment to the scalp and evidently trusted to luck that the burns would not become infected and that they would clear up without any more radical procedure. We have seen, however, that the burns do not remain clean and that they do become infected. If we stop to consider a second degree burn of the scalp, for instance, we are dealing with a devitalized area, burned, both by heat and by the chemical solution in the waving agent (an alkali), with an area over which the superficial layer of scalp has been destroyed by blister formation, leaving an open wound, with an area covered with hair, which is anything but sterile. It is obvious then, that the susceptibility of this area to infection is extremely great. Add to this the common practice by the

beauty parlors, the patients and even by physicians, of rubbing oil or an ointment into this open wound, matting the hair down onto the wound, forming a greasy crust, under which bacteria have an ideal medium in which to carry on their work of reproduction and the destruction of tissue. This often extends deep into the layers of the scalp causing sloughing of fascia, regional adenitis, etc., with resulting scar formation and hair loss.

It is logical then that the principle on which the successful treatment of these burns depends must be the prevention of a medium for the growth of bacteria. This is best done by removing hair, dead skin, grease, dirt, crusts, sloughs, etc., from the burned area and by keeping the wound protected from contamination by a dressing which at the same time allows the penetration of air. With this principle in mind, which after all is only common-sense surgical procedure, the following technic has been used in the treatment of the 15 cases:

1. Careful examination of the entire scalp, as with thick hair, and the usual presence of oil or ointment, a burn might be easily overlooked. The burns are often multiple and scattered over all of the areas of the scalp. This examination should include careful notations as to the number, size, shape, degree, locations, presence or absence of infection, presence or absence of regional adenitis or general manifestations. These cases are liable to have a medico-legal aspect and careful, accurate note taking will save the physician embarrassing situations. (See Fig. 1.)

2. Cut the hair in the region of the burn or burns, with scissors, then shave with a sharp razor over the burn and surrounding the burn for a sufficient area to apply a dressing. This is, of course, painful but is the most important part of the treatment and rarely has to be repeated over the same burn. If this procedure is too painful, especially over a swollen infected burn, it is advisable to do it under ethyl chloride local anesthesia.

3. All foreign material such as matted hair and ointments, burned loose skin, or in infected cases, crusts, sloughs, etc. are

treat the burn caused by heat but to neutralize the alkali which has also been a factor in causing the burn. The waving

FIG. 1. A, Burned area with matted hair. B, Unburned area.

FIG. 2. A, Shaved burned area. B, Shaved area for dressing. C, Unburned area.

removed. Much of this is done with the razor during the shaving. Ethyl chloride is often employed in this procedure, where a crusted, infected area needs to be debrided.

4. The open area is now cleansed with some antiseptic solution; benzine followed by ether or just carbon tetrachloride is very good. Carbon tetrachloride or ether are especially indicated as they not only are good antiseptics but also remove the oil from the scalp, leaving a clean dry area. (See Fig. 2.)

5. This step depends on the presence or absence of infection. In a clean burn of any degree, if not more than forty-eight hours old, freshly prepared 2 per cent tannic acid is used. The patient is instructed to drop a few drops of this solution, using a medicine dropper, through the dressing onto the burn every hour that she is awake for the first forty-eight hours and then every two hours until seventy-two hours have elapsed, after which the tannic acid is discontinued. The burned area should now be well tanned. It is thereafter dressed every few days with dry sterile dressings. Tannic acid is especially indicated, not only to

agent or solution used to moisten the hair before the heat is applied in giving a permanent wave is alkaline, usually containing ammonia.

FIG. 3. A, Sterile gauze dressing over burn. B, Unburned area.

In an infected burn, ichthyol ointment may be used on the dressing followed by the application of flaxseed poultices or a hot-water bottle, to create a local hyperemia in order to localize the infection.

Tannic acid is, of course, not used on the infected burns.

6. A sterile gauze dressing is cut out to conform to the shape and size of the shaved area. The shaved area surrounding the burn is painted, by means of sterile cotton applicators, with a thin and narrow layer of liquid adhesive. A few layers of the gauze are now applied, then more liquid adhesive on the outer border of the dressing and then more gauze. This dressing is very satisfactory as it protects the burn from the hair and other contamination; it does not exclude air from the area; it allows any drainage to be absorbed by the gauze. It makes large cumbersome dressings unnecessary and the hair can be arranged to cover this dressing very readily, which, of course, is an important factor with the type of patient with which we are dealing, and lastly the liquid adhesive is better than collodion as it does not glue itself to the hair and scalp as tenaciously. (See Fig. 3.)

PREVENTION

Much could be said in regard to the prevention of these burns, such as proper instructions to hair dressers, prevention of the neglect in having the burns treated, etc., but that aspect is not in our province to discuss here.

CASE HISTORIES

It might be interesting to give the case histories of 2 rather typical cases:

CASE I. Mrs. M. F., housewife, aged forty.

History. While being given a permanent wave at the establishment of Mr. X by Mr. X himself, ten days previously, the patient complained of excessive heat on the scalp. The patient stated that her complaints were unheeded and that the heat was not turned off until the regular period of time had elapsed. On leaving the beauty parlor she did not realize herself, nor was she informed, that she had been burned.

On arriving home that evening Mrs. F. noticed a blister on the left side of her head to which she applied an ointment. She telephoned her family physician the following day.

He prescribed treatment by phone but did not see the patient. She continued to neglect the burn, but the pain and swelling became more severe and she noticed a lump under her jaw as well as swelling of the face and earache. She finally decided after ten days' neglect that she should put herself under medical care.

Examination showed an infected second degree burn of the left temporal region of the scalp $\frac{3}{4}$ in. in diameter, surrounded by a swollen, red and tender area. Edema of the left side of the face was present as well as enlargement of the left anterior cervical lymph glands. Temperature 100°F. by mouth.

Treatment. The usual shaving was done, also excision of scab and central infected area under ethyl chloride local anesthesia, followed by ichthyol ointment, dressing and advice to use continuous flaxseed poultices.

Progress. The burn was redressed the following day and poultices continued for forty-eight hours, after which the infection had nearly subsided. She was seen a total of 7 times, the last time being fourteen days after the first visit or twenty-four days after receiving the burn.

Result. On the last examination there was a bald spot with hair loss $\frac{1}{8}$ in. in diameter which was practically negligible as it was not noticeable. This is rather remarkable considering the neglect and the severity of the infection.

CASE II. Mrs. V. F., housewife, aged twenty-five.

History. While being given a permanent wave at the establishment of Mr. X by a student operator, a few hours previously, the patient complained of excessive heat on the top of the scalp after the heat had been applied for six minutes. The heat was removed and not reapplied. She did not realize at the time nor was she informed that the burn had occurred, but she was cautioned not to use a comb over the top of her head. This case was not neglected. Treatment was instituted on the same day that the burn was received.

Examination showed 3 first and second degree burns, each about $\frac{5}{8}$ in. in diameter, distributed as follows: (1) midparietal; (2) right parietal; (3) right frontal regions. There was also slight redness and evidence of irritation on the other regions of the scalp.

Treatment. The usual shaving was done, removal of blebs, application of dressings and tannic acid routine instituted.

Progress. The patient suffered pain only on the first day. The burned areas remained clean. The patient was seen only 4 times and on the last visit, which was exactly one week after receiving the burn, the areas were healed and clean.

Result. The patient was discharged on the seventh day with no scar or permanent hair loss. This is, of course, an ideal case.

CONCLUSION

Burns of the scalp in women should be

considered as an important surgical lesion. The results of neglect, delay in treatment and inadequate (conservative) treatment are many, such as infection, resultant scars and hair loss, discomfort and disability. In contrast, dealing with cases that are not neglected, and in which the treatment is not delayed, and in which the treatment consisted of the technic already described, the results were excellent, with no infection, no scars or hair loss, and very little discomfort and disability.

MANAGEMENT OF CONJUNCTIVITIS*

HARRY S. GRADLE, M.D.

CHICAGO

FULLY 25 per cent of the patients that come to an ophthalmologist in a city present some form or other of conjunctivitis and as a result, much of an ophthalmologist's time is spent with this condition. In the majority of cases, a simple inspection of the everted conjunctivae will serve to permit of a clinical diagnosis upon which treatment can be based. In a few cases, microscopic examination of the conjunctival secretion or epithelial scrapings from the conjunctival surface is required for thorough understanding of the case; but for routine office practice, such examinations are required only in the exceptional case. The majority of cases observed fall into one of the following groups:

1. Catarrhal conjunctivitis.
2. Acute or chronic follicular conjunctivitis.
3. Acute or chronic purulent conjunctivitis.
4. Subacute or chronic blepharo-conjunctivitis.
5. Secondary conjunctivitis (due to tear-sac disease, sinus infection, eserine or atropine irritation, etc.).

6. Conjunctivitis of special types as vernal, trachoma, plasmacellularis, etc.

1. *Catarrhal Conjunctivitis.* This is the most common form of conjunctivitis and manifests itself as a simple hyperemia of the tarsal conjunctiva and causes a burning or itching sensation. It is never accompanied by any purulent secretion, but there may be present a soapy foam-like-secretion which is due to the saponification of the excess secretion of the Meibomian glands. This form of inflammation may be bacterial in origin, but is more than apt to be due to some mechanical or extraneous irritation. Good results usually follow the use for several weeks of eye drops two or three times a day, composed of 2 per cent resorcin or 0.5 per cent zinc sulphate or 0.1 per cent zinc chloride in 3 per cent boric acid solution. For the past year, a 50 per cent solution of hexyl-resorcinol has been used with some satisfaction. In this type of case, which may be rather persistent, the armamentarium of the ophthalmologist must be great, for not infrequently is it necessary to vary the character of the astringent used. Among other solutoins that may be given the

* Submitted for publication December 24, 1929.

patients for home use, must be mentioned 3 per cent quinine sulphate, 1 per cent tannic acid, 0.1 per cent dilute acetic acid, and 4 per cent camphor water as an eyewash. A very satisfactory mechanical flushing solution can be prepared by the patients at home by putting into 1 quart of water, 1 teaspoonful each of ordinary table salt, baking soda, and boric acid, and adding, after solution, 1 tablespoonful of glycerine.

2. *Follicular Conjunctivitis.* By acute follicular conjunctivitis is meant that type with massive follicles that can easily be mistaken for trachoma. In this type, expression must be performed and this is best done in the hospital under general anesthesia. Subsequent to the expression, massage forms the mainstay of the treatment. For this, the conjunctivae must be anesthetized and it is preferable to use an anesthetic that does not dilate the pupil, such as 2 per cent butyn or 1 per cent holocaine or 1 per cent tutocaine. The lids are then everted and the conjunctival surfaces rubbed thoroughly with a cotton-wound applicator dipped into mineral oil. The massage is continued for several minutes until the conjunctivae are rather hyperemic. The excess of oil is then flushed off with any neutral solution. For home use, this form of conjunctivitis yields most rapidly to the use of a 1:5000 aqueous solution of oxycyanide of mercury, used in an eye-cup as an eyewash.

As a rule, the chronic follicular conjunctivitis does not need an expression; but it usually is very slow in responding to treatment. The massage with mineral oil as used in the acute form is not sufficiently stimulating and the massaging applicator should be dipped into powdered boric acid or powdered sodium salicylate. This is apt to produce a very mild bleeding from the surface of the conjunctiva, a result that is to be desired. Such treatment should not be carried out oftener than once or at the most twice a week. The same oxycyanide solution should be used at home three or four times daily.

3. *Purulent Conjunctivitis.* The common type of acute purulent conjunctivitis is usually due to a mixed infection by some forms of staphylococci, streptococci, and pneumococci. If the latter organisms predominate, the usual clinical picture presents an additional feature; namely, minute hemorrhages in the conjunctiva, involving the bulbar more than the tarsal conjunctiva. Cleanliness is necessary for rapid recovery in these cases, as well as the frequent use of a bactericidal agent. Seemingly, the most effective of the latter for home use is 1 per cent mercurochrome, used as eyedrops from two to five times a day. If the patient is careless and allows the fluid to overflow the lids, an unpleasant staining of the cheek is produced. This can be avoided by anointing the skin of the lower lid with cold cream before using the solution, removing the cream after all danger of an overflow has passed. Among other solutions that have proved effective in this condition are 4 per cent targesin, 2 per cent sophol, 10 per cent neo-silvol, and 0.5 per cent freshly prepared protargol. If there be clinical or bacteriological reason to suspect a predominance of pneumococci among the infecting organism, 1 per cent ethyl-hydro-cuprein (optochin) should be used as an adjunct. But this alone seldom eliminates the remainder of the infection. For cleansing purposes, any non-irritating solution suffices, for it is only the mechanical flushing of the conjunctival surface that is desired. Boric acid and salt solution (normal) seem to be the favorites.

In chronic purulent conjunctivitis, the treatment is much the same as in the acute forms, but is rendered less frequently. But in addition, it is usually necessary to stimulate the conjunctiva to further bacteriotropic action and for this purpose, fresh 1 per cent silver nitrate is most efficacious. The best results follow instillation without further neutralization with salt solution. It is the practice of some to paint the everted conjunctivae with silver nitrate solution and wash off

the excess of silver with normal salt solution; but this method does not allow the silver to penetrate the recesses of the transitional folds. The instillation of a drop of silver nitrate into the conjunctival sac is followed by a convulsive closure of the eyelids, which tends to spread the solution uniformly over the entire surface of the conjunctiva, including the transitional folds. Neutralization with salt solution is not necessary as the tears perform that function.

4. *Blepharo-conjunctivitis.* Subacute blepharo-conjunctivitis is seldom accompanied by ulceration of the margins of the lids, although there is a crust formation at the roots of the lashes. The conjunctivitis phase has usually preceded the blepharitis phase by a considerable period of time and as a result, there are apt to be many dead lashes visible. These may occur as:

(1) Normally situated lashes with a black root clearly visible through the surrounding tissue and with a shaft slightly darker than the normal lash shaft. When removed, the root is found to be slightly more bulbous than the normal, completely black, and much more flexible than the normal.

(2) Abnormally located new-formed lashes, much more delicate in texture than the normal. These evidently arise from a normal follicle, but emerge through a new formed channel that may lie a full millimeter nearer the conjunctival surface than the normal lash line. The roots of these lashes are also black and flexible, but are not apt to be very bulbous.

(3) Two lashes arising from one normally situated follicle. They are always of unequal size, the larger being the normal lash of that follicle and the smaller, the new-formed pathological lash with a black root. The only abnormality about the larger lash is that it is apt to be somewhat thicker and stronger than its normal fellows.

These abnormal lashes are the result of the peculiar irritation of this form of blepharo-conjunctivitis and their presence

establishes a vicious cycle. The irritation starts the abnormal lashes and the abnormal lashes, by their mere presence, continue the irritation. Consequently, they should all be removed mechanically. Electric epilation is not necessary. In addition to the epilation, the conjunctival irritation must be cared for. Violent treatment is not necessary and these respond well to the local use of 1:5000 oxycyanide of mercury two or three times daily. In addition, the edges of the lids should be well anointed each evening the last thing before retiring. For that purpose, a 1 per cent noviform ointment has given more satisfactory results than the time-honored yellow oxide of mercury ointment. The so-called Betti salve is preferred by some. The condition is not very difficult to control, but is very apt to recur unless treatment is continued for a considerable period of time after all visible manifestations of inflammation have disappeared. Continued recurrences can easily lead to the condition of chronic blepharo-conjunctivitis ulcerosa.

In chronic blepharo-conjunctivitis ulcerosa, small superficial ulcers appear at the roots of the lashes. The size and depth of the ulcers depend upon the length of time that they have existed. Accompanying them is a chronic hyperemia and thickening of the margins of the lids together with a partial or complete loss of the sharp approximating edge of the lids where the transition from the conjunctival to the skin epithelium takes place. The conjunctiva proper shows a condition of hypertrophic inflammation. Meticulous cleanliness of the lid margins is one of the essentials for recovery. The closely adherent crusts must be soaked and then wiped loose from the base of the lashes, not once but several times a day. The ulcers are thus exposed and they should be touched carefully with silver nitrate from 1 to 20 per cent strength. Care must be taken that none of the stronger silver solutions come into contact with the conjunctiva and conse-

quently the excess of silver nitrate must be neutralized completely with salt solution. This treatment should be carried out daily until the ulcerative areas have become epithelialized. For home use instillations of a bland colloidal silver solution have proved efficacious. In addition, it is well to rub into the base of the lashes an ointment containing 2 per cent resorcin and 2 per cent precipitated sulphur in a base of equal parts of lanolin and vaseline. But care must be exercised that none of this is smeared on the conjunctiva for a rather unpleasant irritation is apt to result. After the acute ulcerative condition has been relieved, it pays to modify the therapeutic measures. From here on, the use of fluorescin zinc has justified itself. This is a reddish powder formed by the combination of potassium fluorate and zinc sulphate and is soluble one part to a thousand of water. Upon solution, it reverts to its original constituents. In practical use, a small amount of the powder is rubbed gently on to the anesthetized conjunctiva where it is dissolved slowly by the tears. Thus the conjunctiva is kept bathed for several hours in a weak solution of zinc sulphate and potassium fluorate, which latter is absolutely inert.

It has been found practical to instruct patient in the use of the powder and have it applied daily at home for longer periods of time.

5. *Secondary Conjunctivitis.* But little need be said about secondary conjunctivitis beyond the fact that the diagnosis is the essential feature. There are certain peculiar stigmata to this condition that reveal it plainly to the eye of the practiced ophthalmologist. When once diagnosed, the conjunctiva clears readily following removal of the source of irritation.

6. *Special Types.* It does not lie within the scope of this general paper to discuss the treatment of the special forms of conjunctivitis gathered under this general heading. Each form in itself requires study and therapeutic artistry. Some respond to varied local treatment, others require systemic management, and many will yield only to a combination of both. The therapy of trachoma alone requires many many pages to merely scratch the surface, let alone discuss the non-surgical management of the complications. Consequently, it would seem preferable to postpone discussion of the treatment of the specialized forms of conjunctivitis for some future article.

STENOSIS OF THE CERVIX*

WILLARD R. COOKE, M.D., F.A.C.S.

GALVESTON, TEXAS

THE intelligent treatment of any disease-process must be founded upon an understanding of the causative pathologic conditions: this is especially true in regard to those conditions (for example, stenosis of the cervix) which may be either primary, or merely secondary to some causative condition which is the essential feature of the situation. In the management of cases of stenosis of the cervix the following classification of the under-

lying pathologic processes has been found to be a reasonably satisfactory foundation upon which to build up the plan of treatment in the given case:

I. Developmental stenosis:

1. Simple
2. Associated with:
 - a. Hypoplasia
 - b. Uterine flexion
 - c. Fusion defects

II. Atrophic stenosis:

* Submitted for publication November 16, 1929.

1. Senile
2. After castration
- III. Traumatic stenosis:
 1. Postpartum:
 - a. Occlusive agglutination and healing together of denuded surfaces
 - b. Cicatricial contraction
 2. Postoperative:
 - a. Occlusive agglutination and healing-together of denuded surfaces or edges of flaps
 - b. Cicatricial contraction
 3. Post-radiation: cicatricial contraction and atrophy
- IV. Inflammatory stenosis (specific and non-specific infections):
 1. Endocervicitis, acute and chronic: thickening of the mucosa of the canal
 2. Occlusive agglutination and healing
 3. Cervicitis, acute and chronic:
 - a. Edema and hyperplasia of the stroma of the cervix
 - b. Contraction of inflammatory fibrous tissue
 - c. Cystic cervicitis
- V. Neoplastic stenosis:
 1. Benign:
 - a. Mucosal (fibroadenoma)
 - b. Stromal (fibromyoma, etc.)
 2. Malignant:
 - a. Cancer
 - b. Sarcoma (?)

The neoplastic group (with the exception of fibroadenoma, which rarely gives rise to obstruction of the cervical canal) are not to be considered as suitable cases for ordinary office treatment. In those cases where the stenosis is merely incidental to active or passively active inflammation (endocervicitis, edema, hyperplastic cervicitis, and cystic cervicitis) the stenosis should not be treated until after the causative condition has been relieved by appropriate treatment, because dilatation in these cases does no good and may do harm, and because the stenosis usually disappears as a symptom-producing entity upon the relief of the causative inflamma-

tory process. The treatment of these inflammatory conditions is becoming more and more an office procedure as the proper use and the effectiveness of the small electric cautery is better understood and more and more widely employed. In the presence of acute infection, dilatation is of course contraindicated.

In the developmental group (especially when associated with hypoplasia, flexion or fusion defects), in the cases of post-inflammatory and in some cases of post-operative cicatricial contraction, office treatment will frequently be found to be unsatisfactory on account of the facts that the whole length of the cervix is involved, that the tissues are very resistant to dilatation, and that dilatation of the internal os (which is absolutely essential in cases of developmental stenosis) is difficult and painful. In all of these conditions the cervix must be over-dilated to a considerable degree (40 F.) and the dilatation maintained for a time by a cervical pack (seventy-two hours) or an indwelling tube (three to six weeks, in virginal cases only) if the results of treatment are to be of any lasting duration. Only too often it will be found that a prolonged and uncomfortable series of gradual dilatations is followed by a period of relief which is much shorter than that secured by the single thorough dilatation under anesthesia. On the other hand, it is often possible to afford much relief, where symptoms begin to recur after any form of dilatation, by a single office treatment in the week preceding menstruation (or at varying intervals in menopausal cases). If the treatment room is maintained as a minor operating room, affording adequate assurance of asepsis, practically all of the cases in this group can be treated properly under local block infiltration. By using an extension sleeve (of the type employed in tonsillectomy) the needle can be inserted into the tissues about the cervix without interference with vision. About 20 c.c. of 0.5 per cent novocaine is injected in a collar completely surrounding the cervix,

the points of injection being close against the cervix and the point of the needle just beyond the vaginal wall. If the internal os is to be dilated, the needle is inserted in front of the cervix (at the positions of 10 and 2 o'clock on the clock-face), and passed up to a point just above the internal os, outside the substance of the cervix. At each of these points 10 c.c. of the anesthetic solution is injected after having made sure that the point of the needle does not lie in a blood vessel or in the peritoneal cavity. The solution diffuses pretty thoroughly into the loose parametrial tissues and into the bases of the broad ligaments, affording, usually, a very satisfactory anesthesia for any procedure which does not require much dragging-down of the uterus.

The trophic stenoses (except in hypoplasia), the cases of traumatic and inflammatory occlusion through healing-together of denuded surfaces, and some cases of minor or localized cicatricial contraction (especially post-radiation contraction) form the group in which single or repeated dilatation without anesthesia is especially successful. In using dilators of the expanding type, the screw should never be used to force the blades apart, on account of

the danger of exerting a pressure which may lacerate the cervix; the screw is, however, useful in relieving the muscles of the operator by maintaining the degree of separation of the blades secured through manual pressure. If graduated serial dilators are employed, they should be hollow, in order to avoid the piston action of the solid dilator, which may force infected material or bits of living endometrium into the tubes or into the peritoneal cavity. That this is a real danger may be shown by placing a small amount of bismuth paste in the uterine cavity prior to such dilatation and inspecting the fimbriated extremities of the tubes when the abdomen is opened. The writer has not yet reached any definite conclusion as to the effectiveness of electricity in connection with the treatment of cervical stenosis.

It is impossible to set forth any dogmatic rule in regard to the degree of dilatation and the number of treatments required, as these points must be determined through careful study of the individual case, especially in regard to the sensitiveness of the patient, the mechanical difficulties, and the degree and duration of the relief afforded.

TONSILLECTOMY IN THE OFFICE*

W. W. PEARSON, M.D.

DES MOINES, IOWA

WHETHER tonsillectomy should be performed in the hospital or in the office depends largely upon the office. In a one-man office, with but a single attendant, it is inadvisable. But in an office with a chief, assistants or associates who are thoroughly competent, and nurses who are properly trained for this work, it would seem that this operation can be performed as safely as it can be done in a hospital. We assume that

there is, in connection with such an office, an operating room with an equipment equal to that of any hospital operating room.

Before performing a tonsillectomy it is well to have a report from the patient's physician. Not only must one decide that there is a clear indication for the operation, but one must also be sure that the patient's physical condition warrants it. Before operation a test of the coagulability of the blood is made.

* Submitted for publication December 18, 1929.

There is no reason why the procedure of operation in hospital and office should differ. In the case of adults, my experience justifies a local anesthetic. About half an hour before the time of operation a hypodermic of morphia is injected. There are substitutes for this but morphia acts well in the majority of cases. Everything being in readiness the nurse usually employs cocaine as local anesthetic. This is applied, on a cotton swab, about the fauces and tonsils. A clever nurse may accomplish much in the preparation of the patient, not only by allaying any disposition to nervousness, but also by training in the manner of opening the mouth, in the control of the tongue, and in proper breathing. Next the operator injects the novocaine about both tonsils. A few minutes is required for this to have the desired effect. In the case of the average patient, conversing in an ordinary manner diverts his attention and lessens his anxiety. At this stage equally skillful operators differ greatly in their ability to handle the patient. Confidence, as evidenced by experience and skill, goes far towards making the patient's position less trying. This "vocal anesthesia" is a great help.

When the first tonsil has been removed the wound should be carefully inspected and found to be in good condition before removing the second tonsil. It is well to make an application of iron or an astringent in the tonsil beds. If there is a persistent hemorrhage firm pressure is made, for a time, by means of a good sized gauze pad in a sponge holder.

As to whether the operation has been performed with the patient seated in a chair or reclining upon the operating table is a matter of choice in cases where the patient is under a local anesthetic. The operation being completed, the patient is permitted to occupy a comfortable chair or to recline on a bed. If he is on the bed it is better that he lie on his side as, in this position, the blood and saliva run easily from the mouth and clearing the throat is avoided. The longer this position is maintained the less likelihood

there is of a clot becoming dislodged and of hemorrhage resulting.

In the case of children and unusually nervous individuals a general anesthetic is used. The patient is in a reclining position on the operating table. The table should be inclined so that the head is lowered.

Too deep anesthesia is to be avoided. Aspiration should be employed. In an experience covering more than thirty years I have seen only 2 cases of lung complications and both of these were early in my practice.

Following operation, under general anesthesia, application other than pressure at the bed of the tonsils, to control hemorrhage, is not employed.

At this point we have arrived at the debatable ground as to the respective merits of hospital or office operation. All things being equal I prefer the office operation. The average case, after office operation, rests in the office for two or three hours. At the end of this time the patient returns to his home, to the hotel if accompanied by relative or friend, or to the hospital if there is any reason for so doing, such as a tendency to bleed, excessive nervousness, being alone in the city, etc. In any event he is supplied with telephone numbers of the force so that, in case anything untoward develops, he may call for and receive assistance within a very short time.

In my experience it has been found necessary to use a ligature only a very few times. No patient of mine has been lost from hemorrhage following tonsillectomy.

The patient, being in an operating room, at the office, next door to several surgeons, is assured of better care and more prompt attention than would be the case were he in a hospital in charge of interns with less experience. Should the necessity arise, any one of the doctors in the office could step in and care for him much more quickly and conveniently than could be done were he in a hospital.

There can be no hard and fast rule as

to whether tonsillectomy should be performed at the hospital or at the office. This operation should not be undertaken lightly. There should be well-defined indications for it. The result of the examination by an internist should be had, especially in questionable cases. Even when the surgeon prefers the office operation he must be guided by the condition and wishes

of each individual patient. A careful study of the patient, a thorough knowledge of the location under consideration as to anomalies, an accurate operation, the comfort and safety of the patient; all these should be the controlling factors in deciding which is the more suitable place for performing tonsillectomy, the hospital or the office.

URETHRAL CARUNCLE*

PAUL A. FERRIER, M.D.

PASADENA, CALIF.

URETHRAL caruncle is a distressing neoplasm common in women. While patients may have suffered for years, they are often unable or unwilling to have hospital treatment. An effective office treatment is very desirable.

The cause of caruncle is not known. It occurs at any age, but is most common in mid-life. It may be of any size, from that of a pinhead to that of a raspberry. It may be sessile or pedunculated, but it is practically always located on the posterior rim of the female urethral meatus. At times it is excruciatingly painful. Skene said; "In these extremely painful neoplasms some patients give evidence of constant pain, distress and anxiety; they are pale, emaciated, low-spirited, and wish for death." Some caruncles are not sensitive.

PATHOLOGY

Virchow describes the growth as a vascular polyp. Histologically it is composed of tufts of capillaries in a fibrous and muscular stroma, more or less infiltrated with round cells, according to its degree of inflammation. No nerve endings are found except in the covering epithelium. Cancer has been frequently known to arise on a caruncle.

DIAGNOSIS

It must be differentiated from:

1. Prolapsed urethral mucosa. This, however, will be seen to pout completely around the meatus.
2. Varicosities. These subside when the patient is in the Trendelenburg position.
3. Condylomata. They are generally associated with similar growths on other parts of the vulva.
4. Cysts of Skene's gland.
5. Solid tumors of the urethra. They are rare, and are seldom limited to the area of the posterior rim and are more solid.

TREATMENT

The conditions to be met are:

1. Complete eradication.
2. Restoration to normal of the urethra, particularly avoiding stricture or tractions on the bladder neck.
3. Obtaining a specimen for histological study to rule out malignancy.
4. Minimizing the inconvenience to the patient.

Many methods have been used, but the essential of all is the complete removal of that part of the basement membrane bearing the tumor. Anything less than complete removal is sure to be followed by recurrence. Lawson Tait mentioned a case in which a tumor had been removed every five years for forty years. In some such cases the scarring is more damaging than the original caruncle. Stricture is

* Submitted for publication December 18, 1929.

frequently caused by fulguration or deep cautery.

When a growth is sessile, resection as

its base as recommended by Crenshaw with a slightly curved hemostat, which has been ground flat resembling a miniature

FIG. 1. Urethral caruncle. Centrally, many of the vessels are in loose fibrous stroma; surface is covered by layer of partly squamous and partly transitional epithelium at margin. (From Kelly and Burnam's Diseases of the Kidneys, Ureters and Bladder, D. Appleton & Co.)

practiced by Kelly is necessary, but this is a hospital procedure.

Fulguration is widely used, but it almost always burns too deeply, leaving a heavy scar. The convalescence is unnecessarily long and painful, and stricture often follows. Hot iron and chemical cautery are even more objectionable.

The following method is very satisfactory for all but the broadly sessile type. It is an office procedure, and is a modification of a method suggested by Crenshaw.

OFFICE TREATMENT OF CARUNCLE

The patient is placed in the lithotomy position, and given a thorough soap and water cleansing. Local anesthesia is obtained by a tablet of $2\frac{1}{4}$ grains of cocaine in just sufficient water and lubricating jelly to saturate a cotton applicator, which is inserted into the external urinary meatus. In about five minutes an assistant separates the labia. The urethra is dilated and the margins of the growth defined. The caruncle is then drawn up with a fine Allis forceps and clamped beyond

hemorrhoid clamp. The protruding caruncle is cut off and preserved for section, while the cut edge is carefully cauterized with a very fine electric cautery, such as is used in the nose.

If the procedure is properly carried out only one fine line of cautery is present, which heals rapidly without pain. No postoperative treatment is necessary. After healing is complete one urethral dilation should be done. If the caruncle is so broad that it cannot be included in such a clamp the method is not applicable. In my experience it has been useful for half the cases.

The advantages of this method are:

1. It is an office procedure.
2. It is painless with local anesthesia.
3. There is no bleeding.
4. Immediate relief is obtained.
5. A specimen is available for microscopic diagnosis.
6. On account of the narrow linear scar a minimum of epithelization is necessary, and stricture does not follow.
7. Recurrences are few.

DEPARTMENT OF RADIOLOGY

JAMES T. CASE, M.D., F.A.C.S., EDITOR

INTRAVENOUS UROGRAPHY BY MEANS OF UROSELECTAN*

M. SWICK, M.D.

NEW YORK

THIS work was begun with Selectan Neutral,¹ synthesized by Professor Binz and Doctor R  th and utilized against coccus infections on the Medical Service of Professor Lichtwitz at the St  dtisches Krankenhaus, Hamburg-Altona.² The study of its excretion³ and its iodine content (54 per cent) led to the thought that it might be applicable for roentgenologic purposes. Experiments on rabbits demonstrated the fact that the kidney parenchyma and urinary bladder could be visualized after the intravenous administration of the drug; the pelvis and ureter, on the other hand, were poorly seen. Ligation of the latter did, however, bring the upper tract well into view. Simultaneous studies of its excretion, limited to quantitative determinations of the iodine component, revealed 75 to 80 per cent of the injected iodine in the urine. Save for traces of the latter element in the bile, its pres-

ence in the tissues and feces could never be detected.

Concerning toxicity and tolerance, it was found that 0.2 grams per kilogram of weight could be intravenously administered to the rabbit without any demonstrable ill effects; 0.33 grams per kilogram, however, produced transient generalized disturbances. On the basis of these calculations, one could theoretically give to a sixty kilogram individual eighteen grams of the substance as a maximal dose. Because of marked individual differences in man, the quantity administered was far below the above calculated one. Headache, nausea, vomiting and, in two cases, transient diplopia were disturbing factors. However, there never occurred a reaction severe enough to distract one from pursuing the studies. The oral and rectal administration of Selectan Neutral yielded similar roentgenologic results and toxic manifestations. In all cases the urinary bladder was seen. The kidney parenchyma appeared to stand out more in relief; in two cases of contracted kidneys the reduction in size could be noted. Only on producing a temporary artificial obstruction in the ureter by means of a bougie at the time of maximum excretion was the upper genito-urinary tract outlined, though not very prominently. In other words, the attained results, though not sufficiently good for practical purposes, pointed to the possibilities of further development. The problem then resolved itself into a modification of the substance so as to accomplish the following:

¹ In 1923 Osborne, Sutherland, Scholl and Rowntree were the first to attempt the visualization of the urinary tract by means of intravenous injection of a 10 % solution of sodium iodide. In 1924 Rosenstein and von Lichtenberg repeated the work with iodide in conjunction with the perirenal pneumo-radiographic method of Rosenstein. Volkmann, in 1924, Lenardouzzi and Pecco in 1927, have also given an account of their findings. Hryntschak, at a congress in 1928 and in the *Zeitschrift f  r Urologie*, 1929, reported his work. Finally, Reseno by means of the intravenous use of a substance containing sodium iodide bound to urea was the first to achieve practical results but apparently associated with some reactions.

² Swick, M. *Klinische Wochenschrift* 1929, 8, 2087. von Lichtenberg and Swick, M. *Klinische Wochenschrift*, 1929, 8, 2089.

³ Some studies of the excretion into the bile or urine had been done, though not reported, by Erbach in Prof. Lichtwitz's Clinic.

* Presented by invitation before the Section of Genito-Urinary Surgery, N. Y. Academy of Medicine, Jan. 15, 1930. Work done under a grant from The Emanuel Libman Fellowship Fund.

(1) To diminish the toxicity through the substitution of the methyl group in order to permit the administration of a

FIG. 1. Female, 37 years old Left renal and right ureteral calculi. Both kidneys, pelvis, ureters and bladder visualized, Dilatation of left pelvis and ureter. X-ray taken 15 minutes after injection.

larger dose and thus attain a higher concentration of the excreted iodine component, a determining factor for roentgenologic success. (The observation in two cases of double vision led to the suspicion, at least empirically, that the methyl radical of the Selectan Neutral might be responsible for the toxic manifestations.)

(2) To increase its solubility.

(3) To increase the iodine content of the molecule.

(4) To possibly increase the affinity for the kidney.

Thereafter the work was continued on the urological service of Professor von Lichtenberg at the St. Hedwig Kranken-

haus in Berlin. To eight cases 7.5 grams of the original substance, Selectan Neutral, were administered by mouth with the already described toxic reactions. The bladder was seen in all cases. Only in one case, that of a stone obstruction of the ureter, about one inch below the uretero-pelvic junction, was a useful x-ray film obtained. The further studies, as already pointed out, occupied themselves with the seeking and application of other substances of similar nature with, however, the substitution of the methyl radical.

With the above prerequisites in view; Professor Binz and Doctor R  th of the Landwirtschaftliche Hochschule in Berlin (Chemical Institute) prepared modifications of the original substance. The first because of their higher iodine content, were very poorly soluble in water and unsuitable for intravenous application. Oral administration was likewise inadequate because of their poor absorption by the gastro-intestinal tract. With the reduction of the iodine content and the substitution of the methyl radical, the clinically applicable and successful substance, Uroselectan, was finally obtained.

Uroselectan is non-toxic, very soluble in water, neutral in its reaction, and under normal conditions excreted as such through the genito-urinary tract within eight hours practically to the extent of 90 to 100 per cent, suggesting the likelihood that no chemical reaction takes place in the body. Examination of the blood for the presence of the iodine component fails to reveal it at different intervals five minutes to three hours after the injection. Studies upon the tissues for the distribution of Uroselectan are still in progress. The iodine in the molecule exists in a very stable organically bound state. Neither in solution nor in its excreted form is the iodine present in an inorganic, ionized state. This fact together with the relatively large quantity of the calculated iodine element of Uroselectan that can with impunity be administered would lead one to reason, at least empirically,

why iodism has never been observed. Apparently one can speak of the toxic and therapeutic effects of an iodide when

characterized as the normal "thrust-excretion," present during the first two hours. To illustrate, about three-fifths of

FIG. 6. Female, —5½ years old "Pyelitis." Dilatation of right ureter and pelvis. Twist of right ureter just below uretero-pelvic junction. X-ray taken 45 minutes after injection.

the iodine exists in an inorganic ionized form.

Its tolerance is exceedingly great. To a mouse, seven grams per kilogram of body weight can be intravenously administered without ill effects. As a test dose the same rabbit repeatedly received intravenously three grams per kilogram of body weight. Utilizing the latter dose as a basis for calculation, it follows that 180 grams of the substance, in terms of iodine, 75.6 grams, can be theoretically administered to a sixty kilogram individual.

Quantitative determinations of the excreted substance can form the basis for a functional test. Studies in this direction are still being continued. From the results already obtained, it appears that a normally functioning kidney possesses the ability to excrete this substance with a thrust, that is, a relatively large quantity within a given short period. This can be

FIG. 7. Female, 2 years old. Tumor occupying right half of abdomen. Normal left urinary tract and bladder visualized. Questionable shadow running transversely on right side from crest of ilium to sacro-iliac synchondrosis—renal pelvis. X-ray taken 50 minutes after injection.

the substance is excreted during the first two hours, about one-quarter during the next, and the remainder during the subsequent four hours. Aside from the dose administered and the extrarenal factors influencing renal secretion, the "thrust-excretion" ability of the normally functioning kidney plays a vital role in determining good roentgenologic visualization. In spite of the fact that substance is excreted during the subsequent periods, poor or no visualization is obtained. Good visualization is dependent upon a definite concentration of the shadow-giving element, determined by the factors enumerated. When the additional pathological

factor of obstruction is present, the otherwise normal height of excretion, provided that excretion takes place, is not so essential. Accordingly, visualization or poor visualization or non-visualization of the genito-urinary tract is dependent upon the functional activity. In other words, the concentrating ability of the kidney tissue, irrespective of whether that functional activity be temporarily or permanently conditioned. Therefore, to evaluate the intravenous method of pyelography and to correctly interpret the results therefrom, it is of paramount importance to consider this method an excretory one and to constantly bear in mind the processes occurring in the renal and extrarenal systems, factors determining renal function. The mere non-visualization does not necessarily signify permanent renal functional inhibition, for the secretory activities of a kidney can be temporarily hindered. In addition to anatomical data derived by this physiological route, another vitally important function of the urinary tract that can be studied without the introduction of artificial means is the functional-dynamic activity of the pelvis, ureter and bladder.

Method of administration: For an adult from thirty-three to forty grams are dissolved in doubly distilled water to a volume of one-hundred cubic centimeters. The solution is filtered twice through ordinary filter paper and sterilized in a water bath or autoclave at fifteen pounds of pressure for one-half hour. A child of seven years receives half and a child of two years one-quarter of the dose administered to an adult. The syringe method in preference to that of the gravity is chosen in order to avoid any possibility of foreign-body reaction from tubing. Five to six syringes plus needles are sterilized in distilled water. The injection is done in two stages at intervals of three to five minutes. The first x-ray examination, under usual conditions, is usually made about fifteen minutes after the last injection, the second about twenty to thirty minutes after the first x-ray plate and the third a corre-

sponding period after the second. The number of subsequent plates and the time at which they are taken depend upon the

FIG. 8. Female, 10 years old. "Pyelitis." Both sides visualized, slight dilatation and atony present. X-ray taken 35 minutes after injection.

functional activity and derangement of the kidney. Where the function is poor, it is wise to take subsequent plates roughly at two to four hour intervals and to gage one's course according to the density of the shadow present. Experience alone can guide one.

Reactions: During the injection the patients experience transient thirst and generalized warmth, particularly involving the face and bladder region. Only twice was nausea transiently present. Shivering and vomiting of very short duration occurred in a case of nephrosis (case of Professor von Lichtenberg). To a child of ten (Professor von Lichtenberg's clinic), a case of bilateral insufficiency of the

ureteral orifices with well advanced bilateral pyelonephritic contracted kidneys, about nineteen grams of substance were

lost. In none were there any alarming symptoms or signs observed. It seems that Uroselectan for purposes of intravenous

FIG. 9. Male, 43 years old. Adenocarcinoma of upper pole of left kidney. Left kidney appears to be enlarged. Left upper calyx not well visualized. Right side normal. X-ray taken 15 minutes after injection.

FIG. 10. Pyelogram from below, of the same patient, led to the suspicion of a polycystic kidney.

administered. The child was uremic for a long time previous to the injection (RN 92 per cent). She had had attacks of amaurosis and somnolence. During the latter days there were vomiting and sleepiness. For eight hours after the injection, no reaction set in, subsequently, however, increased drowsiness and gradual cardiac failure were followed by death. Autopsy revealed a marked degree of cardiac hypertrophy, exceedingly severely infected contracted kidneys with double megalo-ureters. There were no macroscopic evidences of drug intoxication. Among the cases examined up to the present, there were children, old people, patients with bilateral kidney disease, patients with prostatic hypertrophy and cardiac disease, and those with active and inactive tubercu-

pyelography is well tolerated and yields practical results.

Its field of application becomes evident whenever ureteral catheterization is dangerous or mechanically impossible; where mechanical or infectious factors of the lower genito-urinary tract prohibit instrumental interference. In the presence of bleeding, and in cases of implanted ureters; in children, and in individuals in whom instrumentation is taxing or harmful, the clinical value of the intravenous method becomes obvious. Its application for pyeloscopic purposes will only be feasible where the density of the excreted substance is sufficient. In other words, its pyeloscopic usage will not be applicable for all cases. Where the function is poor, pyeloscopic results will be correspondingly deficient. In reading the results, one will have to con-

sider the physiological-pathological as well as the anatomical factors. Experience and adaptation will aid in the interpretation

cordially thank Dr. Swick for this really great contribution, and to congratulate him on finally solving this problem that during recent years

and evaluation of the roentgenologic findings attained by this method.

In closing, I want to thank Doctor Stevens and the Genito-Urinary Section for the privilege extended me this evening. In addition, I wish to express my gratitude to Professors Binz, Lichtwitz, and von Lichtenberg for their help and cooperation, and to Doctors Beer and Jaches.

DISCUSSION

DR. BEER: Dr. Swick has just presented one of the most important contributions to general medicine and to urological and general surgery to which I have ever had the pleasure of listening. The great value of this new medium is difficult to evaluate completely at this moment, but without indulging in any ecstatic prognostications as to the wide field of usefulness of uroselectan,¹ I wish to take this opportunity to

¹ The manufacturers of uroselectan, have as yet been unable to distribute more than samples in the U. S. A.

has been attacked by a number of excellent workers.

My remarks I have placed on paper, both for the sake of clarity and brevity. We have just seen a series of clear pictures of the whole urinary tract made by this new method, pictures of such clarity as to be of great diagnostic value. In some of the cases, skilled cystoscopists regularly failed to obtain pictures by the usual cystoscopic methods and therefore definite diagnoses could not be established. In other cases no injections into the ureters could be made as they were implanted in the intestines. These cases show a startling conquest and clear demonstration of the value of this new method.

To one who has had many years of experience

in this line of work, the possibilities of uroselectan are enormous.

Both Swick and v. Lichtenberg vouch for its non-toxicity and its rapid disappearance from the blood. They find it intensifies the kidney shadows, appears in the urine early and in sufficient concentration to produce excellent shadows under the x-ray, both in the pelvis and ureter, as well as in the bladder. Moreover, depending on the renal function, the rapidity and the duration of the excretion of the iodide varies as both Swick and v. Lichtenberg have reported, and as we have seen in the films just presented tonight. An estimate of the iodide output both quantitatively and chronologically may supplement the radiographic functional test.

In view of these facts it must be evident that with uroselectan in the future the general practitioner will, with the aid of the radiologist be able to make periodic health controls of his patients, which will be accurate without relying on time honored and unsatisfactory urine analyses and palpation. In this way, lesions of a surgical character in kidneys, ureters and bladders will be spotted at a much earlier period than at present, when many patients and physicians still dread cystoscopic pyelography.

Another method of studying the motor function of the urinary tract is presented to us perhaps infinitely better than the pyeloscopy practiced at the Necker Hospital, where catheters in the urinary passages may produce all sorts of inhibitory or stimulating effects. Pyeloscopy and ureteroscopy with uroselectan may give us many interesting and valuable new viewpoints, both concerning healthy and diseased urinary tracts.

In a study of 84 cases, v. Lichtenberg states that 61, or 75 per cent gave satisfactory diagnostic data. In 22, cystoscopy with retrograde pyelography was necessary. From his study of the uroselectan, controlled by the usual cystoscopic methods he believes he may conclude:

A. Absence of kidney shadow means (1) no kidney (agenesis), or (2) almost functionless kidneys.

B. Absence may also be evident in extensive tumors, pyonephroses and badly infected obstructed kidneys.

C. Also in bad heart disease with insufficiency.

D. Also in peripheral obstruction with infec-

tion (occasionally bilateral absence of shadow). *On the other hand excellent shadows are obtained in hydronephroses, in ureter stones, kidney stones and other mildly obstructed conditions with fair or good renal function.*

Before closing these appreciative remarks, let me mention some further possibilities of this method, some of which have been touched on by Dr. Swick, and others hinted at by myself.

It is generally believed that if during a resection of the bladder for carcinoma one must sacrifice a ureter, that it does not avail anything to re-implant such a ureter in a new place in the reconstructed bladder. In view of this, many surgeons recommend ligating and dropping the tied ureter. My own experience does not bear out this viewpoint as I have seen such a kidney six years after neostomy with excellent preservation of parenchyma. One such case Dr. Swick has just shown and the study of a series of similar cases and the result of this research will be of great value, as cystoscopic control with catheterization of the re-implanted ureter is usually almost impossible.

Furthermore, there are a fair number of cases where ureters have been cut during operation and have been subsequently re-implanted, the duration of life of such kidneys and their functional activity can probably be studied by the uroselectan method much better than by cystoscopy. We have a series of such cases for Dr. Swick to work on. In addition, cases with ureters implanted in the intestine, such as have been shown tonight, can only be studied and controlled properly by some such method as Dr. Swick has described. Patients who have had pyeloplastic procedures and ureter implantations into the pelvis will also lend themselves nicely to this method. Above all, patients that are not fit for cystoscopy, or who object to the usual repeated retrograde pyelographic methods will benefit by this great improvement.

In closing I must admit that I have been thoroughly stirred by Dr. Swick's excellent work, and congratulate him again, and all of us and our future patients in that he has found the path to successful intravenous pyelography.

DR. ABRAHAM HYMAN: We at Mount Sinai Hospital who have been fortunate enough to follow Dr. Swick's work are just beginning to realize the value of his method of pyelography. It not only opens up new vistas, but will undoubtedly place urological diagnosis on an even more accurate basis than it is at present.

Dr. Beer has already called attention to its possibilities in the field of general medicine and surgery. It appeals to one from many points of view. In the first place, it is an entirely physiological procedure outlining both kidneys, the ureters and bladder from above, and does away with artefacts caused by retrograde pyelography. It also settles once and for all the question of simultaneous bilateral pyelography, a matter which has given rise to considerable adverse criticism during the past few years.

Intravenous pyelography offers an excellent method of studying dynamic conditions within the pelvis and ureter, and from what we have observed so far also gives us a radiographic functional test. To interpret radiograms taken in this way we must, however, change our concepts to some extent. The kidney shadow itself shows up more intensely than in the ordinary pyelogram, although in general the pelvis and ureter are not as distinctly outlined as they are with retrograde pyelography. In the presence of obstruction in the ureter or pelvis the intravenous pyelogram is more intense than in non-obstructive conditions. Its success depends, of course, upon the functional activity of the kidney, a non-functioning organ not being visualized. While this usually denotes anatomical destruction of a kidney, in one case of calculous pyonephrosis the opposite apparently healthy organ failed to visualize and thus brought up the question of the proper interpretation of the absence of a shadow should a kidney be reflexly inhibited. This patient died from uremia following a suprapubic cystotomy for stone performed under local anesthesia. The blood chemistry just before death was considerably elevated although it had been normal prior to operation. Undoubtedly the failure to visualize the kidney was due to a non-functionating organ, and not to a reflex inhibition.

We have had the opportunity of studying by this method a number of selected cases which presented unusual difficulties in diagnosis, and have found it of great value. In several instances the ureters could not be catheterized and the data obtained by intravenous pyelography was of considerable aid in determining operative indications. In a case of ureterocele which had been fulgurated previously a number of attempts to introduce a ureter catheter had failed. No indigo carmine was observed coming from the region of the ureter orifice. The ques-

tion arose as to whether this was a functioning kidney, and intravenous pyelography distinctly showed a moderately hydronephrotic kidney with a ureter outlined all the way down to the bladder. As a result, it was decided to attempt a plastic operation on the lower end of the ureter, which proved successful.

To what extent this method will supplant retrograde pyelography cannot be determined at present but, briefly, it should prove of considerable value in such instances as the following:

The many cases which cannot be cystoscoped or in which the ureters cannot be catheterized for one reason or another.

It will probably bring to light many unsuspected anomalies of the urinary tract.

In urological conditions in children, where it will be especially valuable.

In elucidating many problems which we have hitherto been unable to clarify, notably the dynamics and function of the kidney and ureter after implantation into either the bowel or the bladder.

It will probably supplant retrograde pyelography in tuberculosis of the urinary tract, as in these cases there has always been the danger of unpleasant reactions.

It may help to clarify the situation considerably as far as ureteral strictures are concerned.

In prostatic cases it will undoubtedly assist in demonstrating the condition of the upper urinary tract without resorting to ureteral catheterization.

In closing, let me extend my heartiest congratulations to Dr. Swick for this most valuable contribution to urology.

DR. SWICK, closing: Experience up to the present has not been sufficiently large to permit drawing any conclusions concerning the visualization of uric acid stones by means of this method. Further study is necessary. Compression from without by means of a rubber bag for about 5 minutes prior to the x-ray and then its removal when using the x-ray seems to yield denser pictures.

My experience concerning the restriction of fluid has not been very great, but it seems that it is wiser to permit relatively large quantities of fluid the day previous to the injection. These are points in which we are interested and continuing further studies.

It is important in evaluating and interpreting the results from the standpoint of function, to bear in mind that the functional activity of a

kidney can be temporarily or permanently inhibited and the mere non-visualization at a particular examination does not necessarily mean a permanently damaged kidney. I am referring particularly to a case of two-day

anuria, during which time an intravenous injection yielded negative results. Two weeks later, however, when the function from both sides was normal, a repeated intravenous pyelographic test yielded positive results.

ROENTGEN STUDY OF APICAL CHEST TUMORS*

W. F. HENDERSON, M.D., F.A.C.P.

NEW ORLEANS, LA.

CERTAIN types of tumors located within the chest are sufficiently numerous to deserve a more careful study than has usually been accorded them. The metastatic malignancy involving the pulmonary fields, with its balls of cotton fluff, and the massive or infiltrative carcinoma from some remote primary focus, involving the parenchyma in a widespread involvement, as well as the primary malignancy within the chest, are matters of frequent occurrence in any busy hospital department. The primary carcinoma of the lung originating at the hilum and spreading fanwise in its invasion of the pulmonary fields presents a picture which offers little or no diagnostic difficulty and early becomes familiar to the students of roentgenology. The type of tumor, however, which we wish to present cannot be demonstrated as having origin in the mediastinal structures or the region of the hilum, apparently originating in the apex quite independently of these structures. Pancoast¹ has called attention to several of these neoplasms, and recorded a very excellent review of the clinical, radiologic and pathologic aspects of the subject. It is his opinion that the majority of these have fallen under the classification of primary endothelioma of the pleura, although, as he states specifically, certain of these tumors, lacking necropsy reports with microscopic findings, can only be

so classed in view of their distinct similarity to others which have been fully proved. In our own cases also it is unfortunate that necropsy findings cannot be furnished upon all cases and, along with Pancoast, we again only assume that the similarity of the clinical manifestations, negative physical findings and uniform roentgen-ray observations, which form the basis of the opinion, render these tumors most probably members of the same group in which necropsy has proved the correctness of the opinion.

Roentgenologically, the major facts connected with these tumors seem to be their uniform location in the apex of the chest where they are completely isolated from the hilum, and, since they are not of mediastinal origin, have no tendency to displace the trachea, as is so commonly seen in other types of tumors. Characterized by a lower border which is very sharp and usually almost perfectly straight, there seems to be little or no tendency to invade the subjacent lung tissue, while the tumor as a whole presents a uniform density, quite unlike the mottling or ramifications of the lesions of tuberculosis.

Beyond the lesion in the apex, the chest usually presents no shadows of interest, thus causing the large fan-shaped tumor to stand out all the more distinctly by contrast, while the infrequency of metastasis to more distant locations, and the absence of the habit of forming fluid (characteristics so common in other chest tumors) serve still further to set these

¹ PANCOAST, H. K. Importance of careful roentgen-ray investigations of apical chest tumors. *J. A. M. A.*, 83: 1407-1411, 1924.

* Submitted for publication December 18, 1929.

apart in a separate group of their own. Neither in Pancoast's series nor in my own was fluid observed in any case.

can easily pardon the look of incredulity on the face of a clinician and understand his hesitancy in accepting the findings

FIG. 1. Tumor in right apex. Left base injected with lipiodol.

FIG. 2. Same case as Figure 1. Both bases injected with lipiodol. Secretion from bronchiectasis filling bronchi on right. Tumor in right apex. One month after Figure 1.

A diffuse thickening of the pleura from a previous inflammatory process may possibly serve to confuse, but since this is almost certain to exhibit a reflection off the chest wall at some point near its margin, the differentiation should not be difficult. It may be safely assumed that a tumor which conforms to the dicta just set forth will in all likelihood fall into the classification of pleural endotheliomas.

To this may be added the two outstanding clinical observations: viz., increasingly severe pain in the shoulder, radiating down the arm; and the suprising disproportion between the magnitude of the roentgen findings and the physical signs which can be elicited. In fact, one of the most astonishing aspects of the whole business is the paucity of physical findings during the course of an examination. It has been our experience that under the most careful and skillful physical examination by undoubted leaders of the profession, the ordinary changes of dullness and alteration in breath sounds almost uniformly have been absent, so that one

when the roentgenogram of such a condition is exhibited for his inspection. It seems almost incredible that these tumors should escape detection by ordinary methods of examination, especially when their magnificent sweep is exhibited upon the roentgenogram.

That not all tumors of the apex fall into this classification is of course obvious; we have no intention of contending upon this point. That tumors arising from the mediastinum and extending toward the apex are not characterized by the dicta which we have set forth is frequently illustrated. Reference to Figures 9 and 10 in a suspected case of pleural endothelioma, shows very clearly that this does not have the uniform density, the straight lower margin and the other characteristics which have been described as peculiar to the condition under discussion.

An observation about which no very strong feeling is had regarding its value as a prognostic sign has occurred with

sufficient frequency to justify its discussion. Shortly before death, from three to four weeks, these tumors have exhibited a

In his monumental work on "Neoplastic Diseases" Ewing describes these tumors as "originating in the form of multiple

FIG. 3. Same case as Figures 1 and 2. Sixty days later. Note breaking through of lower margin of tumor. Death shortly after.

FIG. 4. Case III. Elevation of diaphragm on left side. Tumor in left apex. Clinical symptoms, pain in left arm.

tendency to break through the lower margin and to dip down into the structures immediately beneath. In three instances occurring in this series, this has taken place without any demonstrable metastasis to other neighboring or distant organs. That such metastases have occurred, however, cannot be controverted; and, in the light of our deficient autopsy findings, we cannot feel too strongly upon this point, contenting ourselves only with the view that no demonstrable lesions were visible at any point in the osseous system or lungs and that no enlargement of the abdominal viscera could be had. It is likewise true that no symptoms causing suspicion of metastasis to the brain appeared in any of our cases before death. That metastatic invasions do occur in this type of lesion, however, is borne out in Case III. In the absence of invasion the absorption of toxic products must undoubtedly be the occasion of death, since the patients in the terminal stages present a profound anemia and cachexia.

nodules or flat elevations, widely distributed over either the parietal or visceral pleura, or perhaps both. These nodules or plaques fuse to form a dense firm mass which covers and compresses the lung. A serofibrinous or bloody exudate accompanies the growth, which gathers in small cysts or larger collections." This fluid does not become free in the chest, however.

Histologically the structure is rather uniformly that of alveolar and tubular endothelioma. The cells are of moderate size, of polyhedral or flat form, with hyperchromatic, vesicular nuclei and faint nucleoli. They lie in small alveoli or long single or multiple rows between cellular or hyaline connective tissue to which they are usually intimately adherent.

The question as to whether these tumors show a tendency to metastasis has had a large number of proponents on each side. That one case in my own series unquestionably extended to the cervical glands is in accord with Ewing's expressed view, wherein he states: "It

is possible that two groups of serous endotheliomas should be recognized, one invasive, with metastases, and derived

he applied for relief. The blood pressure was noted as 124/80. The heart was declared to offer no clinical evidence of disease. Over the

FIG. 6. Large tumor right apex, previously shown to spring from apex, without hilar connection.

from the endothelium of lymph spaces, and another, superficial, nodular or papillary, and originating from the lining cells." "All agree," says Ewing, "that the process begins over a wide area."

The following case reports may be considered as typical for the entire series:

CASE 1. Mr. A. F. A., aged fifty-nine, was seen through the courtesy of Dr. W. P. Bradburn, March 11, 1926. He had for some years at varying periods suffered from a cough somewhat intractable, more commonly observed in the morning than in the evening, and productive of a very thick, tenacious sputum. He has since childhood noted occasional attacks of semiconsciousness, with rigidity of many muscles in his body. The remainder of the history is without particular interest, other than that the productive cough has been characterized by numerous physicians as bronchiectasis. At the time of the examination, the patient states that for the preceding six months there had been a pain, increasing in severity, in the right shoulder, above the right clavicle and down the arm. This had increased in intensity and it was for this condition that

base of the right lung a few râles could be heard: the breathing was cavernous in type, so that the diagnosis of bronchiectasis, which had stood for some time, was concurred in by Dr. Bradburn. Upon more careful questioning, a history of intermittent hoarseness, the duration of which coincided with the pain, was brought out and the further confidence that upon the morning of application for treatment, a small amount of blood was expectorated. At this time, the patient was referred for otolaryngologic examination, which proved to be productive of no great information, the upper respiratory tract being approximately normal. The roentgenographic examination disclosed a large fan-shaped shadow, apparently that of a tumor, occupying the upper right lung, extending from the apex down to a level slightly below the clavicle. The uniformity of its density, the straight lower margin, and the fact that this could not be demonstrated as arising from the mediastinum, brought forth the expression of an opinion that this was in all likelihood a primary endothelioma of the pleura. (Fig. 1.) A bronchoscopic examination by Dr. Lynch demonstrated a fairly large quantity of mucus coming from the bronchus of the middle and lower lobe, but apparently

none from the upper lobe. The instillation of lipiodol into the lower lobe elicited the shadows produced in Fig. 2, in which the lipiodol is

chest. The pain began to be noticeable in August 1925, occurring at intervals and was associated with some muscular twitching at

FIG. 7. Case 11. Moderately early recognition of tumor in right apex. Not connected with hilum.

FIG. 8. Typical appearance of apical tumor in moderately early stage. Tumor in left apex.

observed to come to rest in the larger bronchi, apparently being arrested upon the level of a fluid occupying these bronchi so that the bronchioles and alveoli are not filled with this substance at any time. Upon the left side no such bronchial filling has occurred, thus allowing the lipiodol to find its way into the bronchioles and alveoli.

Repeated x-ray examination demonstrated no particular changes in the tumor until October 29, 1926, at which time, as observed in Figure 3, a breaking-down of the lower margin and an invasion of the lung tissue at a lower level is seen to have occurred. At this time the pain had greatly increased, particularly down the arm, and a division of the posterior roots was contemplated for relief of pain. Aphonia by this time had become a very definite and distressing symptom. This patient, however, came to his end before a surgical procedure could be undertaken. At no time during the course of the observation was it possible to demonstrate ocular changes.

CASE 11. Mr. R. M., aged thirty-eight, was seen through the courtesy of Dr. I. I. Lemann. The patient presented himself on January 19, 1926, complaining of pain in the

the time of the pain. For the past 2 or 3 months, the pain had been very constant and increasing in intensity. Aspirin at the beginning proved beneficial in 5 grain doses but at the present time 30 grains proved necessary even for moderate comfort. The pain had remained confined to the right chest and down the right arm, the principal point of the pain being above the 4th rib. Prior to coming under our observation, both fluoroscopic and film examinations had produced the report of: "increased density in the right apex, uniform in type without mottling, associated with enlarged peribronchial glands on the right, with a normal heart and aorta. The probability of tuberculosis seems evident."

The general appearance upon presentation to us was of a fairly well nourished, rather sallow anemic individual, 5 feet $5\frac{1}{2}$ inches in height, weight 119 $\frac{3}{4}$ lb.: the heart rate was 80 and upon percussion exhibited normal size and outline. The abdomen was without interest. The pupils were equal, regular and symmetrical, reacting to light and accommodation. The knee jerks were lively and there was noted at this time a marked clubbing of the fingers. The pulmonary examination disclosed an occasional sonorous râle heard upon the right side over

the major portion of the upper half of the lung, and extending out to the axilla. No crepitant or subcrepitant râles could be

mid-way between the arm pit and elbow;" while a further note dated March 11 states that "the pain is still increasing." Morphine

FIG. 9. Tumor of apex suggestive of endothelioma of pleura, except for connection with hilum and fluid formation in right base. See Figure 10.

FIG. 10. Earlier film of same case as Figure 9. Tumor springing from right hilum.

elicited; there was a minor amount of dullness over the right lung in the supraclavicular spaces as low as the 2nd rib anterior and posteriorly as low as the 5th dorsal spine. Over this area there was likewise a suggestion of bronchial breathing.

The patient passed through my hands on January 19, 1926, at which time there was observed a large shadow occupying the entire apex, uniformly dense and somewhat triangular in shape. The lower margin was quite sharp and regular. The homogeneity of the shadow together with its size, position and lack of involvement of either the contiguous or opposite lung tissue was considered to be very suggestive of neoplasm rather than tuberculosis. Further study upon February 18, 1926 failed to disclose any evidence of osseous erosion either in the spine or ribs, nor could evidence of change over the previous roentgenogram be observed. Passing from under our observation, we have a note of March 5, 1926 in which the patient states that "the pain seems to have increased both in intensity and in area. It goes over the chest, down the right arm almost to the elbow, being most intense in the chest just above and to the left of the right nipple, in the armpit and a point

was shortly resorted to pending the division of the posterior roots for relief of pain, but on approximately the 1st of May the picture was terminated by death, the death certificate bearing the notation "carcinoma of the lung."

CASE III. Mr. A. N. M., aged thirty-five, a telegraph operator by occupation, presented himself upon January 14, 1926, complaining of pain in the left shoulder and down the left arm. Approximately four months previous to admission, his attention was called to a stinging, burning pain extending from the shoulder down the arm to reach its point of greatest intensity at the left elbow. Since then this had proceeded down the dorsum of the forearm to the ring and little fingers, and there has been a sense of weakness in the left hand. There now appeared to be a small mass not at all sensitive and considered to be enlarged lymph nodes on the left side of the neck. There was no pain in the neck at any time but there had been a gradually increasing hoarseness for which the patient could not account. The appetite was unusually good and there had been no loss of weight. Aside from the usual diseases of childhood, the previous history was without interest except for an attack of right-sided pneumonia in 1910 which was

uncomplicated. The examination of the nose and throat were without interest, and particular attention is called to the fact that no eye symptoms could be observed. The abdomen was likewise without interest, as was the heart; the examination of the lungs was stated to disclose no evidence of pathology upon either side, and to demonstrate normal breath sounds; that the diaphragms expanded in normal manner; and that, with the exception of a few muscial râles in the left chest, heard intermittently, there was nothing in the chest to attract attention. The pain in the shoulder and down the arm was considered probably dependent upon cervical ribs, examination for which he was referred to me on January 15, 1926. Figure 4 illustrates the condition found at this time. It is scarcely probable that the elevation of the left diaphragm could account for the discomfort down the arm, this being much more probably accounted for by a shadow of uniform density and with straight lower margins without infiltration of the adjacent structures, which is seen to occupy the upper portion of the left lung. A section removed from the tumor in the neck (lymph nodes) brought from the Department of Pathology the diagnosis of neoplasm of the endothelial type, secondary to a primary focus. Further observation was precluded following the patient's leaving the hospital but a subsequent note states that the patient succumbed, the death certificate giving as a primary cause of death, new growth of the left lung.

Contrary to the findings of Pancoast we have observed little or no ocular symptoms, and likewise, contrary to his findings, our cases have been almost uniformly attended with hoarseness, advanced in certain cases to the degree of aphonia. The observation of erosion of the ribs and vertebrae on the affected side

in his cases which presented ocular symptoms would seem to offer the explanation, since the muscle of Mueller, which is the accessory elevator of the lid, receives its major nerve supply through the sympathetic system, this no doubt being involved in the process when extension has become sufficient to produce an actual destruction of osseous tissue. The absence of ptosis of the lid in my own series is therefore compatible with the fact that we were unable to observe erosions of the contiguous bones at any time.

This series to date comprises a total of 8 cases, of which 7 occurred in adults. The ages in the adults lay between the extremes of eighteen and fifty-nine. A single case occurred in a child of two and one-half years which conformed so closely to the changes in the recognized cases that there should have been little doubt as to the true nature of the tumor. This unfortunately escaped detection until the necropsy brought to light the exact pathology. Had I at the time been aware of Hibler's case described by Ewing, occurring in a child of five years, such chagrin might possibly have been avoided. With the exception of the very youthful patient, the series is represented entirely in the male sex who have come from separate sections of the state, and of widely varying occupations. Necropsy reports upon 4 of the 8 cases presented give the cause of death as primary endothelioma involving the pleura. Unfortunately, the remainder of these cases originated in neighboring towns, with death occurring at home, so that no necropsy findings are available for inclusion in this report.

PRACTICAL CONCLUSIONS AS TO THE NATURE AND BEHAVIOR OF GRENZ RAYS (BUCKY)*

DR. MED. B. SPIETHOFF

JENA, GERMANY

GENERAL CONSIDERATION

WHETHER the introduction of the "grenz ray" into practice constitutes a marked advance depends upon whether the tolerance of the skin for these rays is judged greater than its tolerance for the roentgen ray. Since the comparison greatly favors the grenz ray, its excellence in skin therapy, taking similar results for granted, points in two directions. The first leads to a field already conceded to the roentgen ray, although its tilling was not always as fruitful as could be wished since the narrow margin of skin tolerance tied the therapist's hands. It is precisely in this that the grenz ray impressed me at once as significant, for it was possible to expose diseased skin to the alterative effect of the grenz rays for as long as was required to relieve the skin of its perverted form of reaction.

The other direction leads to new territory. The means for administering greater amounts of radiation at a single exposure, and, if necessary, for a long time, opens up a field of work the results of which may be predicated by the possibilities. My reflections relate preeminently to pigmentary nevus, vascular nevus, cavernous angioma and lupus vulgaris. This possibility of employment for the grenz rays is based upon a quality of radiation which excludes injury. According to our experience a tension of 9 kv. max. is recommended. Exceptionally, and only in special cases, as simple sycosis, skin cancer or epithelioma, and in general irradiation, as recommended by Bucky, we use 11 kv. max.

We determine dosage by means of Kuestner's dosimeter in terms of R units, the dosages varying from 70 to 11,000 R. The tube-skin distance is 2 to 70 mm.

The size of the field irradiated varies directly with the distance and has a diameter of from 20 to 70 mm. with our technic. Results as well as prevention of unfavorable effects depend on exact control and continuous corrective regulation of the entire apparatus. The grenz-ray therapist, like others, must master the technic and physics of this method, and must not be careless because the danger is less.

From the onset the importance of exact dosage was obvious to us. For this reason we designedly worked out the precise physical fundamentals from the beginning. Dr. Kirsch, an assistant in my clinic, and Dr. Gfroer, a physicist, developed in the physical laboratory of my clinic a system of measuring, which has met all requirements. Bucky's approval, when visiting our clinic, was of great satisfaction to us. The essence of the method is the determination that each apparatus actually presents the kilovoltage at the tube which is claimed by the manufacturer. These conditions must be controlled continuously. Kirsch tests this out with a large Hartman and Braun kilovoltmeter in connection with a large hot cathode valve tube. But individual tubes may vary considerably in their ray intensity in spite of equal tension (construction of tube and thickness of Lindemann window). Therefore the output of the tube must be determined exactly. The best way is to check and control the energy in R units by means of an ionometer. We use Kuestner's device for this purpose.

General therapy, as practiced by Bucky, has great and, in my opinion, growing value, just as has local treatment. No doubt, a profound effect is exerted on the entire organism, the vegetative system and duct-

* Submitted for publication December 18, 1929.

less glands, alone and in combination. In the course of general radiation, following Bucky's directions, *general* and *local* reactions arise, the former indicated by exhaustion, weariness, loss of appetite; the latter, cutaneous, through increase of the pathologic condition. As secondary effects we often observed regulation of formerly somewhat irregular menses, stimulation of the flow, a general increase of vitality of the individual, indicating a profound constitutional effect. When talking of by-effects we use this expression in regard to the skin disease which gave the indication for grenz-ray therapy, and do not consider these effects of secondary therapeutic importance.

A striking example of this sort was the case of a seven-year-old child, backward mentally and physically, dull, listless, undernourished, depressed, a poor eater. In his early infancy a skin affection began as multiple keratoderma of the palms, soles, genital region, perineum, and about the mouth. He was bald, even without lanugo. His spinal fluid and Wassermann test were negative, and the sella turcica normal. During the first series of general applications, local and constitutional reactions took place, but improvement of the general and skin conditions occurred soon after. Eight weeks later a second series followed. The local and general condition improved steadily. The boy began to eat well, became animated and cheerful. There are now hardly any pathological changes left in the skin, which never had been treated locally. The hair appeared and steadily increased.

Another case was not so favorable. The condition was similar, but more severe. The child was twelve years old when treatment was begun. The third series of irradiation brought about no improvement except in a vague general sense, greater ability to concentrate and pay attention. A previous rectal incontinence was controlled.

A case of extensive spontaneous gangrene of the skin is worth mentioning. Generalized irradiation had the effect of

controlling outbreaks save for a few slight ones. The treatment is not yet completed. This patient is referred to, not as an example of a cure, but for the purpose of indicating the usefulness as to the discovery of new indications for its use. Another observation was made after intensive local irradiation in a twenty-year-old girl with severe and extensive eczema dating from childhood, not of the constitutional leptosomous type described by me, often seen in eczema, but of the athletic pycnotic sort. She was adipose; she took no further reductive diet since it had been ineffectual before grenz ray treatment. Gradually her weight dropped and stayed normal after local treatment on large fields with a tension of 9 kv. max. This must have been caused by the effect of the grenz rays on her ductless glands. The explanation might be the peculiar result of the decomposition analysis of the endocrine organs according to Abderhalden by means of the interferometric method after Loewe-Hirsch. Before the treatment the thyroid secretion is largely decomposed, but, if after irradiation the weight becomes normal, no decomposition is present.

No undesired reactions were ever observed by us with 9 kv. max. and an intensity up to 11,000 R.

In another interesting and important instance in which a pigmentary nevus had been treated with 11,000 R, ulceration took place. It differed from a roentgen ulcer by being practically painless and superficial, and because it healed completely and rapidly. At times itching, slight erythema followed by brownish to dark brown hyperkeratotic scaling, or exudative erythema occur. Such reactions may arise within from a few days to five weeks after exposure.

As to repeating treatments, I favor interruptions of one week after 230 R, two weeks after 460 R, and three to four weeks when the dosage has been greater. I never resume treatment before the reaction has disappeared.

SPECIAL INDICATIONS IN SKIN DISEASES

Eczema (subacute, inflammatory): 110 to 220 R.

Eczema (chronic): 460 R.

Pruritus with lichenification (Vidal): 460 R.

Psoriasis: 230 to 460 R.

Chronic, keratotic, thickened lesions: 920 R at times with heat (sensibilisation).

Scalp: 460 to 690 R every fortnight.

Lichen planus: Like psoriasis.

Dermatitis (active): 460 R.

Rosacea with acne: 230 or 460 or 690 R.

When there is a great deal of acne formation I use filtered x-rays, or grenz-rays, 11 KV tension, and about 4000 R. Recently I add, at Bucky's suggestion, general irradiation, if local does not suffice. Its influences on the flushes is excellent. General treatment is indicated. With such a procedure sometimes the reaction after local treatment fails to appear. Diet and medical treatment (aconite, sulphur) of the flushes are necessary besides.

Acne varioliformis: 460 R, diet; Alpine lamp in the intervals.

Perniones: 920 R.

Scleroderma and the sclerodermatous form of idiopathic atrophy: 1380 R.

Keloids, spontaneous and cicatricial: 2300 to 4600 R, at times with heat.

Lupus vulgaris: Simple form, 4600 R with heat or 11,000 R with intervals from two to four weeks according to reaction.

Ulcerating form, 4600 R fortnightly.

In scar tissue, 4600 R with heat.

Verrucous form, necrogenic verruca, tuberculosis verrucosa as ordinary form, 4600 R with heat or 11,000 R.

Erythema Induratum: Darier's sarcoid, lupoid Roeckl: 4300 R with heat.

Lupus erythematosus: Experiences with this therapeutically difficult and incalculable dermatosis are the same as with other methods: both unsatisfactory and excellent results. Reaction cannot be foreseen and even exacerbations might follow. I begin with a low dose: 110 R, at two to three week intervals. If necessary and possible I go up to 460 R at intervals of two to six to twelve weeks. Reactions must always be allowed to subside. Therapeutic effect often slow; therefore, patience is necessary.

Verruca vulgaris: 4900 R with heat.

Juvenile warts: 460 R. If necessary 690 to 920 R.

Nevus pigmentosus: 4600 R. Repeat till results are satisfactory.

Nevus pigmentosus fibromatosus: 4600 R with heat.

Nevus vasculosus (flat): 820 R with intervals of four to five weeks. Improvement often is delayed.

Tumor vasculosus: 1380 R.

Alopecia prematura: 460 R at intervals of four weeks.

Sluggish ulcers (irrespective of cause): 4600 R at intervals of two weeks.

Sycosis simplex: Success in my experience, as in Bucky's, depends upon whether the areas have been previously treated with the roentgen rays or not. If they have been, the outlook is poorer. 11 kv. max., 1425 R (Bucky).

Skin cancer, Epithelioma: 9 kv. max. do not suffice; 11 kv. max., 4000 R (Bucky), much better.

ENDOTHELIOMYELOMA OF THE PUBIS WITH GENERALIZED METASTASES

CASE REPORT*

CHARLES MURRAY GRATZ, M.D.

NEW YORK

THE patient, J. H., a girl, seven years of age, was perfectly well until June 23, 1928, when she slipped and fell in the bathtub, resulting in an injury to the region of the symphysis pubis. The trauma was so slight that it attracted little attention until July 10, when her parents first noticed that she walked with a slight limp, favoring the left leg. From July 13, she complained of definite pain when moving the left hip though the distress was somewhat relieved by rest.

At the request of Dr. Irving Okin of Passaic, New Jersey, I saw the case in consultation on July 15. Physical examination at that time showed slight atrophy of the upper third of the left thigh and very slight limitation of motion of the left hip with slight pain in the extremes of motion, particularly abduction and hyperextension. Pressure over the symphysis pubis elicited no pain. There was, however, a definite enlargement of the left inguinal lymph glands. The patient had been running a slight fever of about 1°F., and had a slightly positive von Pirquet reaction. The urine at that time was positive for Bence-Jones protein. The rest of the examination, carefully checked, was negative.

Dr. Okin ordered an x-ray examination on July 13 which showed a destructive process starting just to the left of the symphysis pubis and also extending downward on the ischium; the lesion was further complicated by the pathological fracture.

Provisional diagnosis of primary bone tumor with pathological fracture was made at the time of consultation. Other possibilities considered in making a differential diagnosis were:

1. Osteomyelitis.
2. Tuberculosis.
3. Secondary bone tumor.

Further x-ray films of the lungs were requested, to be followed by x-ray therapy. The patient was placed in a spica and kept in bed in the interval.

It is of interest to note that the films of the lungs taken at this time were regarded as negative by myself and several other doctors, but when compared with films taken October 22, it is possible that metastases noted on the later films may have been present even then.

Further x-ray studies were made on July 30, (Fig. 1) which were reported by Dr. R. Herendeen as follows:

The entire left pubis is the seat of a destructive process and is irregular in outline, lacking normal density. There are no localized areas of destruction or reaction and no sequestra are seen. The changes usually noted in osteomyelitis are not seen. The medullary portion of bone seems slightly widened, but the most significant finding is the diffuse infiltration which gives to the films the features frequently noted in endotheliomyeloma or Ewing's tumor. The acetabulum is clean-cut in outline, as is also the head of the femur. The epiphyseal lines in this region show no changes. In this respect, the condition does not follow the usual methods of involvement in tuberculosis. Roentgen diagnosis: Endotheliomyeloma.

Clinically and radiologically, we felt justified in making a final diagnosis of endotheliomyeloma with pathological fracture, and x-ray therapy, as first suggested at the time of consultation, was carried out by Dr. R. Herendeen. The details of this treatment follows:

Treatment 1, July 30, 1928.

Area, left groin anterior.

Spark Gap: 10 in.

Filter: 4 mm. Al.

Distance: 12 in.

Ma: 4

Time: 7 min.

Treatment 2, August 2, 1928.

Area, left groin anterior.

Spark Gap: 10 in.

Filter: 4 mm. Al.

Distance: 12 in.

Ma: 4

Time: 8 min.

* Submitted for publication December 18, 1929.

Treatment 3, August 16, 1928.

Area, left hip, a.p.

Spark Gap: 10 in.

Filter: 4 mm. Al.

Distance: 12 in.

Ma: 4

Time: 10 min.

Treatment 4, September 6, 1928.

Area, left pelvis anterior.

Spark Gap: 10 in.

Filter: 4 mm. Al.

Distance: 12 in.

Ma: 4

Time: 10 min.

Treatment 5, November 18, 1928.

Area, left pelvis anteroposterior.

Spark Gap: 10 in.

Filter: 4 mm. Al.

Distance: 12 in.

Ma: 4

Time: 10 min.

Record of radiation to the lungs, after pulmonary involvement was found, was as follows:

Treatment 1, November 9, 1928.

Area, left chest anterior.

Size of area, 4 × 4.

Spark Gap: 175 k.v.

Filter: 0.5 mm. Cu.

Distance: 30 cm.

Ma: 30.

Time: 5 min.

Treatment 2, November 21, 1928.

Area, right chest lower posterior.

Size of area, 6 × 6.

Spark Gap: 175 k.v.

Filter: 0.5 mm. Cu.

Distance: 30 cm.

Ma: 30

Time: 3 min.

Treatment 3, November 26, 1928.

Area, left chest anterior oblique.

Spark Gap: 175 k.v.

Filter: 0.5 mm. Cu.

Distance: 30 cm.

Ma: 30.

Time: 3 min.

Treatment 4, November 29, 1928.

Area, right chest posterior oblique.

Size of area, 6 × 8.

Spark Gap: 175 k.v.

Filter: 0.5 mm. Cu.

Distance: 30 cm.

Ma: 30.

Time: 3 min.

Treatment 5, December 1, 1928.

Area, left chest posterior oblique.

FIG. 1. X-ray film of July 30 showing extent of involvement at this time.

Size of area, 6 × 6.

Spark Gap: 175 k.v.

Filter: 0.5 mm. Cu.

Distance: 50 cm.

Ma: 30.

Time: 6 min.

Treatment 6, December 4, 1928.

Area, right chest anterior oblique.

Size of area, 4 × 6.

Spark Gap: 175 k.v.

Filter: 0.5 mm. Cu.

Distance: 30 cm.

Ma: 30.

Time: 3½ min.

In addition to above, radium pack was used to the left pubis by Dr. William B. Coley on December 15, 1928, as noted later.

It is interesting to note that during the first part of this treatment, there was a definite improvement in the child's condition. The cast was kept in place to prevent any possibility of further fracture, and in the latter part of August 1928, the films were shown to Dr. William B. Coley and our diagnosis was confirmed by him. Further x-ray studies were made on October 18, 1928 which showed a definite increase in severity of the destructive process. Accordingly, renewed examination of the lungs was made and we found that these films (Fig. 2) showed a definite pulmonary involvement. Further consultation with Dr. James Ewing as well as Dr. Herendeen confirmed the original diagnosis of endothelio-

myeloma, and Dr. Ewing advised continuing x-ray therapy to include the lungs, and further suggested that Coley's toxins might be of

made as comfortable as possible. There was gradually increasing emaciation and the patient died on May 5, 1929.

FIG. 2. X-ray film of October 22 showing definite pulmonary metastasis.

value in conjunction with x-ray therapy. The latter was carried out at the Hospital for the Ruptured and Crippled beginning October 23, 1928, after the case had been seen in consultation with Dr. Coley and under his immediate direction. Dr. Coley's report was as follows:

The toxins were started on October 23, 1928, beginning with $\frac{1}{4}$ min. gradually increasing until 3 min. were given on November 4, resulting in a reaction up to 104° .

Further roentgenograms showed no increase in the size of the tumor, but a small round metastasis appearing.

From November 9 to December 1, toxins were omitted as she was receiving x-ray therapy. They were again started on December 3 and continued on the 7th, 9th, 11th and 13th the last on the 18th of December, when the dosage of 7 min. was given. Radium pack was applied on December 15.

For the first two weeks, the x-ray studies showed some increase in both the pelvic tumor and the metastases. Films taken December 5, showed no increase in the tumors of the lungs over the ones taken November 17 (Fig. 3). On December 22, x-ray showed a very definite increase in the pelvic tumor, which cannot only be shown by x-ray but was definitely palpable. There was also an increase in size of the tumors of the lungs.

The patient lost weight steadily. General condition became decidedly worse. It was felt that nothing could be gained by further treatment of toxins and radiation. The patient was advised to be taken home and

FIG. 3. X-ray film of November showing marked increase in size of tumor.

AUTOPSY REPORT

Anatomical Diagnosis. 1. Endotheliomyeloma of pubis.

2. Metastases to lungs, pleurae, liver and diaphragm. Implants on bladder and peritoneum.

3. Purulent cystitis.

4. Ascending renal infection; pyelonephritis.

General. Body of an emaciated female child. Abdomen markedly distended. There was marked edema of left leg and marked emaciation of right leg. On opening the body, 1 liter of straw-colored fluid escaped from abdomen.

Bladder. Distended, contained about 500 c.c. of slightly cloudy urine.

Lungs. Studded with opaque tumor nodules varying in size from 0.5 to 4 cm. Both lungs adherent to parietal pleura, which in turn was studded with tumor tissue. The tumors were firm, opaque without necrosis, and some projected from the pleural surface in polypoid form.

Heart. Normal in size. Right ventricle slightly thickened. Valves normal.

Stomach. Negative.

Intestines. Markedly inflated with gas. Two minute skin metastases appeared over the inguinal region.

Kidneys. Pelvis dilated. Turbid, purulent urine.

Spleen. Slight postmortem decomposition. No metastases.

Liver. Much enlarged, extended completely across mid-abdomen. Two-thirds of organ replaced by tumor tissue. Gall bladder distended with fluid bile.

Gross Description of Tumor. The tumor arose in the left pubic bone, involved this bone, the ischium, nearly the whole of the ilium, the acetabulum and neck of femur; all of which were encased in the mass of tumor tissue and largely destroyed thereby. Tumor also involved the wall of the bladder, entire mass measuring $20 \times 18 \times 15$ cm. On section it had a peculiar lobulated arrangement and the texture was of a fine, spongy character

with very little necrosis. There was a pathological fracture near the head of femur.

Microscopic. *Endotheliomyeloma.* The tumor tissue was composed by medium-sized polyhyal and rounded cells with large vesicular nuclei which were very hyperchromatic and made up most of the cell. These cells were arranged in columns or rosettes, or they grew diffusely. The rosettes represented imperfectly formed capillary blood vessels. There was very scanty cytoplasm. Mitoses were not numerous. The blood supply was furnished by very numerous vessels of the type of arterioles. About many of these arterioles the tumor cells grew in masses of radiating rows.

ROENTGENOGRAPHIC VISUALIZATION OF APPENDICAL PERFORATION*

JOSÉ ARIAS AVELLÁN, M.D.

HAVANA, CUBA

AT THE suggestion of our friend, Dr. Case, we venture to offer for publication this modest contribution to radiology which at the same time serves as a demonstration of the imperious necessity of considering radiology in its proper place as a valued aid to medicine, perhaps standing first among such aids, to be resorted to always, not only in the solution of enigmas or as a recourse when all other auxilliary means of diagnosis have failed, but to correlate and corroborate the results of other investigations.

In the case which I have the pleasure of reporting, we see an excellent example of this statement that radiology should always be looked upon as the first aid in every examination.

Clinical History. B. F., white, twenty-three years of age, native of Spain. She has had two normal births and one miscarriage at two months six months ago. She has suffered the usual diseases of children: measles, whooping cough, etc.

Present Illness. The patient suffers frequently from pain in the head and very acute

pains in the shoulder and in the right lumbar region. She points to the lumbar region as the source of her pain. She does not remember having passed stones nor having observed blood in the urine. The pain has been noted every six or eight months and has lasted one to three days; but with a purgative and with hot applications in the lumbar region, relief has been obtained. At the present attack the intensity of the pain grew more acute than ever before and vomiting and nausea supervened, this being the occasion of her admission to the clinic of the Hijas de Galicia.

On examination the internist gave an opinion that the patient was suffering from renal colic, for the relief of which he ordered morphine and the application of an ice bag.

On the following day, the surgeon, Dr. Rodriguez Bas, on his visit found the patient complaining of very severe pain in the lumbar region, radiating toward the right hypochondrium, with slight muscular rigidity limited to that region. Pressure did not awaken pain in the cecoappendicular region (McBurney's point) nor in the remainder of the abdomen where there was noted slight gas distention. Temperature was 38°C . (100.4°F .), pulse 120.

Examination of the blood showed 16,000

*Submitted for publication January 18, 1930.

leucocytes, of which 76 per cent were polymorphonuclears, 20 per cent lymphocytes, and 2 per cent mononuclears.

The patient was referred on the following day to the x-ray Department for investigation of a possible lesion of the small or large intes-

FIG. 1. Barium enema, showing at arrows barium which has escaped from perforated appendix.

Examination of the urine showed 550 c.c., containing pus cells and traces of albumin.

The patient remained in bed with ice bags, the pulse and temperature falling until they reached normal on the fifth day. The muscular rigidity having now practically disappeared, it was possible to note on palpation a deep resistance, somewhat intermittent and somewhat painful, in the right hypochondrium.

A new examination of the blood showed 7000 white cells with 48 per cent polymorphonuclears, 5 per cent eosinophiles, and 2 per cent mononuclears.

A new examination of the urine showed a specimen of 775 c.c. with numerous pus cells and traces of albumin.

Radiological Examination. Study of the urinary tract showed no suspicious shadows; in fact, nothing abnormal. The pelvis of the right kidney was then visualized with iodide of sodium and it was evident that the calices and the renal pelvis were normal and that the size, position and form of the right kidney were normal.

FIG. 2. More detailed roentgenogram showing clearly appendix and spilled barium in appendicular abscess.

tine. For this she was first given an opaque enema which was observed under the fluoroscopic screen. Imagine our surprise when, after the cecum had been filled by the enema, there was presented to our sight the astonishing aspect which is brought out so clearly in the roentgenograms which illustrate this paper. The cecum was high and fixed by adhesions. The appendix was large and retrocecal, filled for its entire extent, but permitting the escape through its distal extremity of some of the opaque liquid of the enema, the escaped barium being distributed in an irregular form radiating from the free extremity of the appendix. The x-ray examination was terminated with films made anteroposteriorly and posteroanteriorly and the surgeon was immediately informed that the diagnosis was acute perforated appendicitis with subhepatic plastic peritonitis.

The surgeon ordered rest, ice bags, opium, and strict liquid diet, and so twenty days passed, at the end of which time the patient was operated upon.

Operation. Anesthetic with gas and ether. Presno's high incision for the biliary tract, extended somewhat downward. On opening the peritoneum there was noted a small

quantity of seropurulent liquid and in addition many pericolic and pericecal adhesions fixing the cecum in a high position with the appendix extending upward along its posterior aspect. When the adhesions around the appendix had been freed, it was followed down towards its base where there was encountered a perforation about 2 mm. in diameter, extending upward toward the inferior aspect of the liver. After ligating the mesoappendix the appendix was removed with a cautery and the wound closed layer by layer, placing a drainage tube and gauze down toward the inferior surface of the liver. The patient was discharged, cured, twenty-one days after the operation.

It is quite indisputable that if this patient had been examined with the x-rays some

months previous when her only complaints were the right lumbar pains, it would have been relatively easy to have formed the opinion that the trouble was probably due to this large, long, retrocecal appendix which caused the pain to radiate into the lumbar region. This could easily have explained the symptomatology and early operation would have avoided the serious risk of life incurred by this patient.

So then permit us once more to beg of our medical colleagues that the more intimate the collaboration with the radiologists, the more surely will good results be obtained. In this particular case the patient's life would not have been placed in such jeopardy.

CONGENITAL RADIOULNAR SYNOSTOSIS*

WITH REPORT OF CASE

EDWARD S. BLAINE, M.D.

CHICAGO, ILL.

THIS title refers to a rare developmental fault occurring in the upper forearm in an exceedingly small percentage of individuals of the human species. The condition will be of interest to the surgeon, the orthopedist, the roentgenologist, and those who are concerned with studies in anatomical detail. Having encountered one of these unusual anomalies, my attention has been focused on the subject to the extent that it seems worth while to report the case in detail together with correlated matter bearing on the subject.

This condition has also been called "congenital pronation" because of the inability of the subject to supinate the hand; in other words, the palm cannot be turned upward because the wrist is in fixed pronation. Another term given is "congenital fusion of upper ends of radius and ulna," which describes the anatomical variant.¹

Following the advent of the x-ray in the

investigation of the skeletal structures of the body, the presence of this lesion has been discovered in a number of instances but it was known in the pre-roentgen era through post-mortem studies. Apparently it was first discovered by Lenoir in 1817 at autopsy, according to Mouchet.² Prior to the discovery of the x-ray, there are records of 15 cases found post mortem and 7 in vivo, described by Abbott³ in 1891. Upwards of 200 cases of this lesion are recorded in medical literature. Kienböck⁴ in 1910 reported several cases, Baisch⁵ in 1912 described 4 cases and referred to 38 others including those of Keinböck; Sonntag,⁶ Lüdin,⁷ Grashey⁸ and Köhler⁹ are among those who have written on this rare lesion. Boorstein in 1918 wrote on the subject.¹⁰ The most illuminative presentation in English on radioulnar synostosis is the extensive article by Davenport, Taylor and Nelson,¹¹ who jointly made a most thorough excursion into various fields in the study from many angles of the 15

* Submitted for publication January 18, 1930.

cases which they found to have this lesion.

Radioulnar synostosis is a congenital

in Figure 1, from which it will be seen that there is no regular pattern of occurrence.

One female appears to have been affected

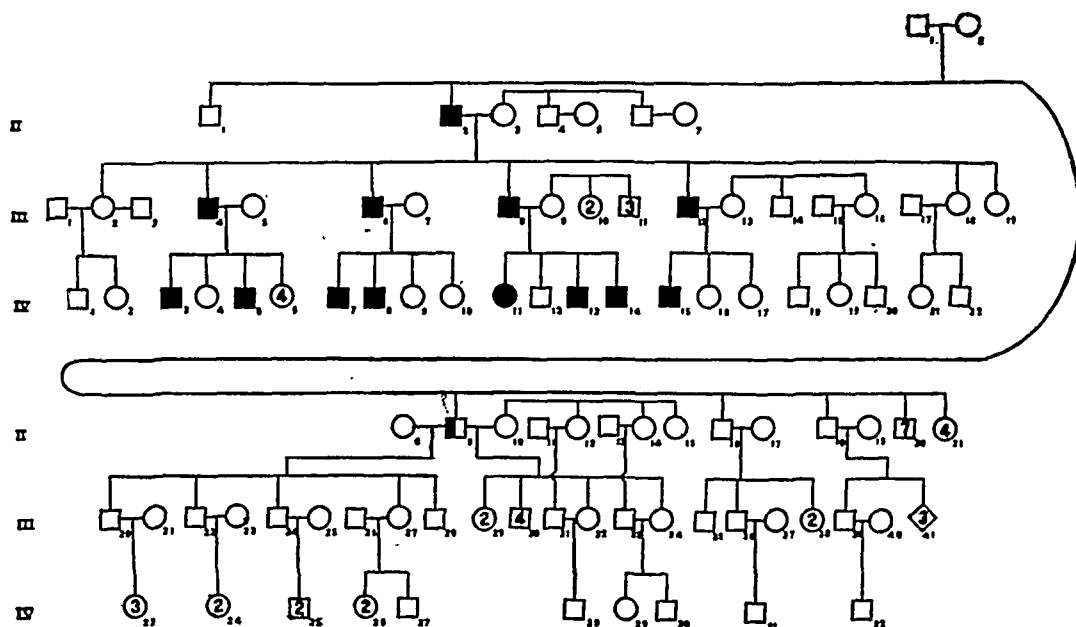

FIG. 1. Pedigree chart of M. family: Roman numerals represent generations; arabic numerals, individuals. Squares represent males; circles, females; black symbols, synostotic individuals; half-black, those unilaterally affected. Large figures inside symbols indicate designated number of that sex. Line of Generation II is carried down to second level to conserve space. (Davenport, Taylor and Nelson.)

fault which consists of the fusion of the upper portions of the radius and ulna in a greater or less degree of pronation due to which supination is impossible. The amount of fusion of the bones varies from 1 to 6 cm. in length in the reported cases. In a little more than 50 per cent of the studied cases the condition was found to be bilateral and occurred far more often in males than in females. In several of the cases it was found to have occurred in successive generations of a family line but a careful analysis of successive issues in other families in which the lesion occurred, failed to show such a familial sequence. In certain strains this peculiar synostosis appears to be of a dominant Mendelian character. The evidence seems to show that while its appearance does not exactly follow the Mendelian formula, it is possible that some complex variation of this theory may be involved. In one family investigated by Davenport, Taylor, and Nelson, they found the inheritance to be as shown

in the four generations shown and one case of unilateral involvement is indicated. The extensive involvement and sequence found in this one family is not duplicated in the pedigree charts of any of the other families studied by Davenport and his associates, who found that the occurrence of synostotic individuals in successive generations is far less frequent than is recorded in this particular family.

CASE REPORT

The case which came to my notice is that of A. B. C., a graduate in medicine. He is twenty-eight years of age, white, and weighs about 165 lbs. He is of robust or stocky build. His appearance is not unusual although one may note a seemingly short neck, and the upper and lower extremities appear somewhat shorter than normal in relation to the length of the body. He is in splendid health and there is no history of a major injury to either of the upper extremities. Just prior to entering school at five years of age, a minor injury to the right wrist occurred when it was first noted that

he could not turn his hand in supination. There were no untoward events in connection with the prenatal or obstetrical periods, so far as

upper, the fork being held in a vertical position. In receiving coins, etc., he cups the left hand and can thus retain the object being handled

FIG. 2.

FIG. 3.

FIG. 2. Right radioulnar synostosis (Author's case).

FIG. 3. Left radioulnar synostosis (reversed in reproduction, Author's case).

can be ascertained. No similar occurrences are known of in the two preceding generations. He is somewhat handicapped in that he is unable to rotate either of the forearms. The left forearm is fixed in a position midway between pronation and supination, that is, about 90° , while the right forearm is fixed in nearly complete pronation, lacking about 15° . This enables him to use the left hand to a much greater degree than the right. In writing he has relatively little difficulty in holding the pen and writes a legible hand. In eating he has difficulty in handling a spoon and fork with the right hand and holds these as does an infant, that is, sideways with the fingers folded around the handle. In loading the spoon or fork, the elbow is held high and then brought in toward the body to place the food in the mouth. In using the knife he has no difficulty but holding the fork in the cutting operation is a rather awkward procedure, accomplished by placing the thumb and little fingers on the under side and the remaining fingers on the

with very little difficulty. Flexion and extension of the forearms are not restricted or interfered with. Both wrists, both hands and the fingers all function in a normal manner.

An x-ray investigation of the case reveals a bony fusion of the radii with the ulnae (Figs. 2 and 3). The synostosis amounts to about 4.5 cm. on the left side and 6 cm. on the right side. The bony texture is normal in every way and the union of the two bones is complete in every way. The fusion extends to the articular surfaces which are continuous. Only the outer portions of the upper ends of the radii can be recognized but no real radial heads are present. The lower portions of the radii and ulnae show no structural changes except that both ulnae are longer than normal, thus obliterating the area of the triangular fibrocartilage which is always present in the normal. No bone or joint variations were found in the neck, upper spine, lower thighs, knees or upper legs. It thus appears that the radioulnar synostosis is the only fault present.

The type revealed in this case is the deformity found in the typical cases described by most of the authors who have reported this lesion in detail. Variants in the lesion are many. In most cases the forearms present different degrees of the pronation deformity, right and left, as regards the fixed position of the hands and lower forearms; this was true in the case here reported. In most of the cases described the integrity of the elbow joint was not altered, the articulating surfaces being smooth and regular. In a considerable number of cases there was an absence of the head of the radius, this structure being represented by no more than a rounded upper end instead of the flattened knob form as seen in the roentgenogram of the normal. This has been called the "headless type."

In seeking an explanation for this peculiar anomaly, one may consider the possibility of it being an atavistic throwback, for a somewhat similar development is found in the radius and ulna of the deer. These two bones are separate in the young deer but they normally become fused in the matured animals. One may also cite a similarity in the fusion of the several bones that form the human skull where fusion and resulting obliteration of interosseous spaces are a normal sequence with advancing years. In none of the many cases reported have I found any reference to any accompanying synarthrosis of the nearby elbow joint.

A study of the two bones involved in this peculiar bony union from the phylogenetic standpoint reveals certain aspects which may have some bearing on its formation. It has been shown that the fins of fishes are the forerunners of the body appendages in man, namely, the hands and feet. In the amphibia the number of bones distal to the humerus is reduced to two, one of which, the ulna, is posterior, containing the elbow process or the olecranon, and the other, the radius, lies anteriorly supporting the carpus. It will be noted that when a child crawls prior

to learning to walk, it acts as a quadruped and in so doing the radius is crossed in front of the ulna, but when it attains the erect posture, the plane of the lower ends of the radius and ulna turn outward 90° , that is, they supinate and thus assume the sagittal plane. In the ungulates, such as the horse, deer, etc., the ulna is rudimentary and, as has been noted in a previous paragraph, in the older deer the radius and ulna regularly undergo a fusion of their proximal portions. In bats, also, the radius and ulna are fused in like manner.

Embryological consideration of the subject under consideration reveals that in the earlier weeks of development of the human embryo, the arms grow outward almost perpendicular to the long axis of the torso and thus lie at right angles to it. They soon become flexed and turn medially so that the palmar aspects of the hand lie applied to the front of the chest. Thus the opposite ends of the ulna and radius become reversed in position. In this position an x-ray projection of the normal bones would present an appearance of fusion of their upper ends due to overlapping, while the distal ends, not being superimposed, would be seen to be separated. Thus there is a relatively close approximation of the upper ends of the radius and ulna at this stage and it is conceivable that certain postural pressures would cause an increased contact or squeezing together of the apposing surfaces of the upper ends of the ulna and radius which might result in a mutation fault of development, the two bones becoming blended where the direct contact occurred. Another angle of the situation will be recognized in the fact that both of these bones arise from a single precartilaginous unit in which two centers later appear, one for each of the two bones of the forearm. Thus a synostotic state normally occurs in the early embryonic stages of growth. The event of an incomplete separation of these two centers may explain the occurrence of radioulnar synostosis. This failure of sepa-

ration may or may not be an inherited trait; in some strains it appears definitely proved to have been inherited, but in other cases investigated it apparently is not a transmitted characteristic. In the case being reported the patient knows of no other such occurrence in his family antecedents. Being a physician, he has made a thorough study of the situation and thus we may rely on his statement that there is no other involvement in his family line.

It has been observed that in certain families in which synostotic individuals occurred in several succeeding generations they were all of short stature, while the isolated occurrences appeared in individuals who were not short or of the pudgy habitus.

In several instances of radioulnar synostosis, multiple cartilaginous exostoses were present, which condition seems to be related to the lesion under consideration but the connection is not closely defined. The occurrence of other bony defects such as club feet, club hands, absence of certain fingers and toes, fusion of fingers, etc., has also been noted in a number of the reported cases of radioulnar synostosis. Having these concomitant conditions in mind one may classify the lesion under consideration as in the achondroplasia group. This lesion is ordinarily considered as an inherited lesion but in the subject of this report, no other similar instance in the antecedents has been discovered, as already stated. In the group of cases in which heredity plays a part, the inheritance is always in the male line, and it is bilateral in about 50 per cent of the reported cases.

Note is made of the relatively greater occurrence in families in which there are consanguineous unions. Davenport et al.¹¹ say:

It may be remarked that a large proportion of the families we have studied at first hand are Jewish and thus belong to a race in which consanguineous marriage is relatively common. Thus, of our 13 families, 9 are Jewish, 1 German, 1 French Irish, 1 Irish and 1 English . . .

On the whole, the evidence seems to favor the conclusion that there is some truth in all of the hypotheses and that radioulnar synostosis is a trait that, in different biotypes, depends on one, two or three factors; that it is usually an autosomal dominant (although the possibility that the gene for it may lie in the chromosome of certain families should be kept in mind), and that it is partially sex limited but variable in degree of expression, possibly owing to modifying factors.

In their summary, the same authors present the following:

1. Radioulnar synostosis varies greatly in degree. Two fairly distinct types may be distinguished; (a) the type in which the radial head is absent, the proximal end of the radius being fused with the ulna, and (b) the type in which the head of the radius is displaced toward the flexor side of the arm. The extent of the bony union varies from about 2 to 6 cm.

2. A comparative review of the mammalia shows that the radius and ulna are frequently united. This union is associated partly with their close proximity, so that any overgrowth of either bone may cause a permanent fusion of the two. When the use of the anterior appendage is not seriously interfered with, this union may become normal for a species, genus or family.

3. The radius and ulna develop out of the same precartilag plate, and, at a later stage, the perichondrium of the two bones is continuous at their proximal ends.

4. The abnormal developmental impulses which lead to synostosis are indicated by other bony defects in the propositus or his family. Among the commonest of these are; exostoses, clubfoot, and clubhand, flat-foot, abnormally diminished growth of long bones, short stature and bowlegs; in general, dyschondroplasia.

5. There are genotypical differences in the various families, which thus belong to diverse biotypes. In one family (M.) only one gene appears to be responsible for the synostosis, and this acts much as though in the Y chromosome (but this is highly uncertain). In most families, distribution is that of a two-gene trait; in one of the families, of a three-gene trait. The synostosis is always a dominant trait.

6. Males are twice as likely to be affected

as females; and this result holds for bone defects in general.

7. Frequent lack of symmetry in the defect suggest that there is frequent imperfection of dominance.

8. Consanguineous matings are found in the synostotic families; and it is probable that they are especially frequent in them.

9. Radioulnar synostosis appears to be a dominant partially sex-limited trait, which varies in degree of expression.

The essayist has endeavored to find record of successful corrective treatment for this condition but in most of the cases reported in which surgical attempt was made to provide relief, the effort proved unsatisfactory. Dawson¹² describes an operative correction in which he speaks of having obtained an excellent result by a six-step operation covering a very extended period of time.

HEAD SLING TRACTION TECHNIC IN CERVICAL SPINE ROENTGENOGRAPHY*

PHILIP LEWIN, M.D.

CHICAGO, ILL.

THE accompanying diagram (Fig. 1) illustrates a method of making roentgenograms of the cervical spine, which is useful in certain cases.

S. S., a man of thirty-eight years, was playing handball. He hit the ball and, in an attempt to get out of another player's path, rotated and hyperextended his head, neck and thorax. "Something" happened to his head, neck and chest. A torticollis developed gradually and in eighteen hours arrived at the stage shown in Figure 2. He had severe pain over the left supraclavicular and infraclavicular regions.

Roentgenograms were made by Dr. E. L. Jenkinson without and with traction as shown in Figures 3 and 4. The traction was obtained by tearing a longitudinal slit in a piece of muslin (see Fig. 1B). One-half was placed under

the chin, the other under the occiput. Both ends were pulled upon by an intern while the exposures were made (see Fig. 1A.). Note the relative positions of the elongated transverse processes of the seventh cervical vertebrae, the first ribs and the transverse processes of the first thoracic vertebrae.

The sling may be made from a strip of heavy roller bandage about 48 in. long and 6 in. wide. A linear slit about 10 in. long is made through the middle.

The treatment indicated in this case is, very briefly: head traction in bed with the head of the bed elevated 8 in. and the application of a weight of about 12 lbs., and after a few days the application of a very high Schanz collar made of cotton, bandages and adhesive.

* Submitted for publication January 18, 1930.

THE COST OF MEDICAL CARE VS. THE VALUE OF MEDICAL SERVICE

INABILITY to differentiate between the cost of medical care and the value of medical service is costing thousands of lives and millions in money. Many who have had experience in the stock market will appreciate the vast difference that may exist between cost and value. Professional services, like some stocks, may cost a great deal and still be without value. The cost of anything is unsatisfactory unless the value is known.

The cost of medical services may be determined without a great deal of difficulty. The value cannot be estimated with similar ease. It may range anywhere from a restoration of the patient's health and vigor to a virtual death warrant. Yet the cost in each case may remain the same. For example: What is the value of a doctor's services who carefully studies a case of intestinal obstruction until it is

hopeless? What is the value of his services when he appreciates the dangers of delay and relieves the condition safely? And finally, what is the value of his services when he mistakes a diaphragmatic pleurisy for an intestinal obstruction and an ill-advised operation results in an untimely death? The doctor's charge may be the same in each case.

Let us not think for a moment that the surgeon is the only one who needs watching. The American obstetrician has the highest mortality rate in the entire civilized world. We are all familiar with the studious internist who treats stomach ulcer, curing it time after time until perforation or malignancy intervenes to put an end to the tragedy. We have met the popular society doctor who treats all comers for what they have financially. Usually he treats them for not less than \$250.00,

never hesitating to treat them for more if they have it. We must not inadvertently overlook the practitioner who takes a six weeks' vacation and returns a "specialist," reminding one strongly of Chick Sales' character described under the same title.

In the event the patient's malady is obviously surgical he is generously referred to the surgeon offering the largest rebate. Even in this line competition seems to be keen. One operator, I shall not call him a surgeon, is reported to have remarked: "There is no money in surgery any more because the referring doctor demands 75 per cent of the operating fee for referring the case." The man referring the case ignores the fact that incompetent surgery is taking a toll of human lives ranging from 10 to 50 per cent.

The cost of medical care has increased to an alarming degree in the past twenty years. As a *science* Medicine has made greater advances than the increase in cost. In the practice of the healing art such has not been the case. On the contrary the art of medicine has actually retrograded until the regular profession occupies a position only a little higher, on the average, than the irregular.

Only a few years ago Dr. Willis, of Richmond, read a paper before the meeting of the American College of Surgeons showing a steadily increasing mortality rate attending many of the common surgical procedures. He showed that the mortality rate attending goiter operations had increased 250 per cent; operation mortality rate for gallstones had increased 77 per cent; duodenal and gastric ulcer operation mortality rate had increased 72 per cent, and that for appendicitis had increased 31 per cent.

While on the average the work has become poorer the cost has at the same time increased. Cost is no criterion of the worth of medical care. Frequently the better paid, the poorer are the services.

The variation in the value of medical services is almost beyond comprehension.

As an example: Quoting from Carr and Deacon on "Appendicitis in Michigan:" "In some counties no deaths occurred. In others it varies from 1 per cent and over. In only 8 counties was it less than 5 per cent; in 11 it was between 5 and 10 per cent; in 16, between 10 and 14 per cent; in 17, between 14 and 18 per cent, and in 10, between 18 and 21 per cent. In 10 it was 21 per cent or more." This will give an average of approximately 15 per cent. Compare this, if you please, with the mortality rate of competent surgeons which does not run over 1.5 per cent. A difference of 1000 per cent between the *average* and the *good*. In other words, there is a sacrifice of more than 13 human lives in each 100 suffering from appendicitis, and an appendectomy is a simple operation! Probably one person in each one hundred has been operated on for appendicitis within the past ten years. In other words, one million people in this country have undergone this operation during that time. If there was a preventable loss of 13 in each hundred, there was a preventable loss of 130,000 in the people residing in the confines of this country during ten years; 13,000 each year, or 36 per day. This is part of the needless cost paid in the treatment of appendicitis. No wonder the average mortality shows a greater increase in the more difficult operations of gall bladder and stomach ulcer; and still greater in that attending goiter operations where the difficulties of the operation are further complicated by the patient's poor physical condition. This needless sacrifice of human life constitutes the greater cost of medical care. The cost will always be unsatisfactory until the value is determined.

At first it may not be practical that individual mortality rates be determined for general information. It is essential that each hospital have its classified results available to every prospective patient. For example: The prospective appendicitis patient has a right to know that in hospital "A" there is a mortality

rate of 2 per cent while in hospital "B," which is likewise an accredited hospital, there is an average mortality rate of 15 per cent. This knowledge may be embarrassing to the hospital with the high rate but the patient whose life is at stake has the right to know.

Members of the regular medical profession has been responsible for increasing the average length of human life nearly two decades within the past half century. Shall we sit quietly by while fanatics, irregulars and incompetents nullify this splendid work so well begun.

Human life is too valuable to be squan-

dered at the rate of 1000 per cent here and more there. The banker figures a fraction 1 per cent profit or loss. If the medical profession is going to be worthy of the confidence and trust of the people it must purge itself of the corruption and incompetency that is polluting it and costing thousands of lives.

When medical services are sold on the basis of efficiency and not by high pressure salesmanship then there will be no argument about the cost of medical care. The patient gets what he pays for and pays for what he gets.

CHARLES EATON PHILLIPS, M.D., F.A.C.S.

CLINICAL RADIOLOGY

THE work of the radiologist is not a mere technical task of producing a set of shadow records. More than most other branches of surgical diagnostic and therapeutic performance, radiology demands a preparation for the work, requiring practical familiarity with many technical and physical facts and a multitude of details of mechanical technic. For the physician engaged in the field of general radiology including both diagnosis and therapy, the requirement comes close to that paragon, the "all round" specialist, for x-ray methods now constitute a part of the armamentarium of almost every specialist in medicine and surgery. The radiologist does well to select a certain sphere of medical investigation for his chief endeavor.

Before commencing the strictly medical part of his work the physician-radiologist must go through a more or less mechanical procedure to produce a shadow record on screen or film. To a certain extent, but never wholly, this part of the task may be sublet, so to speak, to trained technical medical and lay assistants, and the real work of the physician-radiologist begins when the shadow record has been produced. These shadows must be trans-

lated into terms of pathology and clinical medicine; and whereas a certain part of the preliminary technical labor may be sublet to assistants here the radiologist must do the work himself, and do it as a clinician if his work is to be of real value. The greater his familiarity with the clinical aspects of the case before him, the more likely is his effort to prove worth while.

Radiological work is in large measure a consultation, though we fear it is seldom considered in that dignified light. In the ordinary consultation, as carried out in daily surgical practice, the consultant is given the advantage of all the data of history, physical findings and laboratory tests available in the case up to the moment. The consultant seeks to uncover new facts and from his experience tries either to put new construction upon the interpretation or to confirm or deny the hypotheses already advanced. How rarely is this really done in radiological practice! The age and general aspect of the patient speak for themselves, if the case is one requiring the personal attendance of the physician-radiologist, but the history and other data are available usually only by special effort, which is so time consuming

that in a busy x-ray department it is seldom put forth. Many referring physicians seem loath to write down a working diagnosis on the refer-blank accompanying the patient to the x-ray department; sometimes it is not possible to give a preliminary diagnosis. But as a matter of fact, the radiologist does not need a working diagnosis; he does need to know the motive which led the referring physician to ask for x-ray study.

Father would not ask Johnnie merely to go and look in the basement; he would say, he thought he heard a noise, or felt a draft, or smelled gas, or heard water trickling, or suspected a prowler, or forgot to turn off the draft in the furnace, and he would ask the boy to look in the basement because he feared such or such a thing was wrong. Or, he might tell the boy to explore the basement, not because anything was thought to be wrong, but just to make sure all was right.

Again, Johnnie might be asked to go to the upstairs front room and look—not just *to look*, but *to look for something*. However definite or indefinite the suspicion, Johnnie would be given some idea as to why he was to look.

So, in referring patients to the x-ray department for diagnostic work, it would be extremely helpful if the referring physician would write down in a brief sentence the real reason for the reference. A tentative diagnosis is not necessary, but a phrase or a sentence acquainting the radiologist with the problem would make the latter's work more efficient and pleasant, and result in much economy of material and time.

Some problem always presents itself to the attending physician suggesting the value of an x-ray study. The radiologist needs to know what is this problem. In chest cases, is the examination suggested because of a cough? Is the cough productive or not? Is there dyspnea? Is it a pulmonary or a cardiovascular problem, etc? Is there a question of subphrenic abscess? In the latter case the technic of

the study will be very different from the usual chest examination. The same is true of suspected pericardial adhesions. Suspected rib fracture requires a special kind of radiographic study.

Of course in the case of Johnnie already cited, there may have been instituted in his home a formal routine of exploration of the house, and at father's behest Johnnie might make the complete round, checking up on leaking gas, blocked sewer, open windows, unlocked doors, leaking faucets, intruders, etc.; but what a lot of wasted effort in the average instance!

In the interests of more efficient radiological work, let us urge a closer cooperation between the surgeon and his radiological colleagues. Let him take the radiologist sufficiently into his confidence to briefly state his problem: the reason for sending the case for x-ray investigation. If, as sometimes (not often enough) the examination is being done as part of a complete physical inventory, let this be stated; the radiologist will be stimulated perhaps more than ever to extra effort to unearth some hidden and as yet symptomless lesion.

Although his duty and his pride of technical work well done require him to take an active interest in the preliminary technical work, the real function of the physician-radiologist commences with the interpretation of the shadow findings, on the fluoroscopic screen or on the films. The surgeon in his physical examination endeavors to visualize in flesh and blood the lesion he palpates. In his mind's eye he sees a cyst, a fibroid, a tubal mass, a polyp, a distended gall-bladder, not merely a tumor. Guided by the history, he interprets abdominal rigidity, epigastric and lower right quadrant pain, more or less fever, and nausea as a frank appendicitis, and in his mind he pictures the inflamed rigid appendix, possibly with fragile recent adhesion bands or gangrenous tip, and fibrinous peritoneal exudate. Similarly, the radiologist must visualize in flesh and blood what he sees in shadow: not a niche, a filling

defect, a displacement, an enlargement, a contraction, a thickening, a light or a shadow, but the actual lesions. In his mind he must picture the ulcer, the cancer, the tumor, the stricture, the cavity. This ability comes only from experience and is relatively impossible without a basis of experience in pathology or surgery. Lack-

ing this foundation, much can be done to qualify the radiologist for more efficient interpretation by working *with* him, giving him opportunity for pathological or surgical check on his findings and aiding him in his effort to practice radiology as a clinician.

JAMES T. CASE.

INTRAVENOUS UROGRAPHY

DURING recent years, a number of men, including Rowntree and his associates, Roseno, Hryntschak, Rosenstein and von Lichtenberg have been striving to obtain a medium, which, injected into the circulation or administered by mouth or rectum would produce definite x-ray pictures of the urinary organs.

Up to date, most of these attempts at what we may call briefly intravenous urography, have failed, through occasionally in obstructed cases fairly clear pictures have been obtained. It was left to Dr. Swick of this city, while working with Professor Lichtwitz, and subsequently in von Lichtenberg's clinic, with the aid

of Professor Binz and Dr. Raeth, to solve this important problem.

As a result of his work, we have an iodide compound, known by the trade name uroselectan, which, administered intravenously in non-toxic doses, produces with some regularity, strikingly perfect pyelograms, ureterograms and cystograms. The great value of this new method of exploration of the urinary tract is difficult to gauge so soon after its introduction. It is already evident, however, that uroselectan is going to revolutionize many aspects of medicine, surgery, urology, and radiology.

EDWIN BEER.

Subscribers to THE AMERICAN JOURNAL OF SURGERY visiting New York City are invited to make the office of the publishers (Paul B. Hoeber, Inc., 76 Fifth Avenue, New York) their headquarters. Mail, packages or bundles may be addressed in our care. Hotel reservations will gladly be made for those advising us in advance; kindly notify us in detail as to requirements and prices. List of operations in New York hospitals on file in our office daily.

“BUCK’S EXTENSION”

GURDON BUCK was a product of New York City. He was born on Fulton Street on May 4, 1807. His father and mother were grandchildren of Governor Gurdon Saltonstall of Connecticut.

Gurdon Buck went to Nelson Classical School and finally made up his mind he wanted to be a physician. So he studied, as was the custom in those times, under Dr. Thomas Cock, and in 1830 received his M.D. from the College of Physicians and Surgeons, now a part of Columbia University. He interned in the New York Hospital. Having finished his hospital training he migrated to Europe, this being the “ultra” method of adding the finishing touches to an education, and in Europe he continued his studies in the hospitals of Paris, Berlin and Vienna for a term of two and a half years.

In 1836 he made a second visit to Europe, and in Geneva, Switzerland, married Henrietta E. Wolff of that city.

He returned to America and in 1837 was appointed visiting surgeon to the New York Hospital. This position he held until his death. He also was appointed visiting surgeon to St. Luke’s Hospital and the Presbyterian Hospital at the time of their organization. In addition, Buck was visiting surgeon at the New York Eye and Ear Infirmary, from 1852 to 1862.

He was a Fellow of the Academy of Medicine from the time of its organization, and served as its vice-president for one term. He was a member of the New York Pathological Society and served one term as president. As would be expected, he was a member of his County and State medical societies.

As a surgeon he was remarkable for his boldness in operating, and the thoroughness of the detail of his after-treatment. He was particularly devoted to fractures and spent hours in the wards of his hospitals studying this type of surgery. As a result he revolutionized the current system of treatment. The improvements he inaugurated in the then-existing apparatus are brilliant chapters in surgical history.

His method of treating fracture of the thigh by the weight and pulley was at once recognized by the profession throughout the civilized world as the establishment of an original principle of great value. To this day it is known as “Buck’s extension.”

Buck’s investigations with regard to the pelvic fascia are to be found in the first volume of the *Transactions of the American Medical Association*.

His joint surgery was especially creditable in a preantiseptic era. He excised the elbow joint¹ and the knee joint². He was successful in treating edema of the glottis, and was deeply interested in rhinoplastic, stomatoplastic and other reparative operations, publishing a work of some 237 pages in 1876.

Buck was a very religious man, charitably inclined to the poor, and his sense of professional honor was Puritanical in its idealism.

He died of uremic poisoning on March 6, 1877. He left a widow, two daughters and three sons, two of whom became doctors of medicine.

BOOKSHELF BROWSING

ON THE ALLEGED PENETRATION OF THE HUMAN URETHRA

BY AN
AMAZONIAN CATFISH CALLED CANDIRÚ

WITH A REVIEW OF THE ALLIED HABITS OF OTHER
MEMBERS OF THE FAMILY PYGIDIIDAE*

PART II

E. W. GUDGER, PH.D.

NEW YORK

WHAT IS THE CANDIRÚ?

THAT there are various fishes in the Amazon and its tributaries called candirús by the inhabitants of the country is certain, and that they are nuisances, blood-suckers, either as ectoparasites or endoparasites on fishes, beasts and man himself, is equally certain. Let us see what can be done to identify some of these candirús as members of the family Pygidiidae, and of the subfamilies repeatedly referred to.

The first teller of the candirú story is Martius (1829) who thinks our fish to be the young of either *Cetopsis candirú* or *C. coecutiens*, or possibly of a third unidentified species, a thing impossible of determination since his specimens of the last were lost. However, it is significant that he makes *candirú* the specific name of one of his fishes. Eigenmann (1918b) scouts the *Cetopsis-Candirú* idea for, although this fish is called by that name, it grows to

be at least a foot long and 2 inches thick. However, Martius indicates that he suspected the young of some species of this genus, and Mr. John Tee-Van collected at Kartabo, Mazaruni River, British Guiana, in 1919, a little *Cetopsis* 28 mm. long and 3.5 mm. in greatest diameter, small enough easily to have penetrated the human urethra. Presumably these fish are not parasitic, but it should be noted that the *Cetopsidae* and the *Pygidiidae* live in the waters of the Amazon and hence the young cetopsids might easily consort with and be captured along with the pygidiids.

In the search for all the first-hand information possible about the candirú, I was referred to Dr. Alfredo da Matta of Manaus, as the outstanding physician of that part of Amazonia and a man much interested in natural history. I asked him for data and his long letter to me (which will be frequently referred to) shows a large acquaintance with the candirú and

* Part I appeared in Vol. 8, No. 1, p. 170, January, 1930.

associated fishes, and has thrown a flood of light on various points. Among other things, he thus clears up the matter of Martius's candirú:

The Candirú must not be confused with the Candirú-nassée. The Candirú is a small fish . . . without scales, of the genus *Vandellia*, family Trichomycteridae [Pygidiidae]. The Candirú-nassée, while it is also scaleless, reaches a much larger size, and is the common name of the species, *Cetopsis coecutiens*.

To return to the chronological order, the next account is from Poeppig (1836) who collected numbers of his candirú in Yurimaguas. His only preservative was the raw spirit of the country distilled from the juice of the sugar cane, and in this they unfortunately spoiled. However, examination of the figures in Spix and Martius showed him that his fish was quite unlike theirs. One can only conjecture that his candirú was a *Vandellia* or a *Stegophilus* since *Branchoica* has thus far not been taken in the Amazon basin.

Castelnau (1855) gives a colored figure of his candirú (identified as *Trichomycterus pusillus*) marked natural size. It is about 145 mm. (5.75 in.) long. This figure shows the operculum well provided with large spines. Eigenmann renames this fish *Pareidon microps* Kner, and his figures show the opercular spines fitted for holding the fish in position, while the maxillary and mandibular teeth are possibly adopted for scarification. However, its considerable size and its terminal mouth hardly adapt it for endoparasitism. It is undoubtedly carnivorous and possibly an ectoparasite, but hardly an endoparasite unless when young. It does not seem worth while to figure it herein.

Wallis (Müller, 1870) collected a candirú in the Huallagua and sent it to the Leipzig Museum where it was provisionally assigned to the genus *Trichomycterus* or to *Stegophilus*. In 1888 Leuckart loaned it to Lütken who after a careful study decided (1891) that this fish was a new form and gave it the name *Acanthopoma annectens*. The name still stands, and inspection of Lütken's figures (Figs. 1, 2, and 3 herein)

leads to the conclusion, based on the slender form, the spinous opercles, the shape and form of the ventrally placed mouth, and the teeth, that the fish (100 mm. long) is a blood-sucker, a candirú.

Boulenger's (1898a) specimens, sent in by Dr. Bach from the Rio Jurua, were found identical with those sent to Lacépède from Lisbon in 1808 by Prof. Vandelli (*Vandellia cirrhosa*) without indication of their source, but, as we now have every reason to believe, coming from Brazil. As the figures (4 and 5) show, we have here a slender fish with retentive opercular spines, with premaxillary teeth fitted for rasping and with a suctorial mouth. It is easy to believe that this "Candyrú" is also a parasite, and, as the ventrally placed opercular spines show, one not necessarily confining its operations to the gills of fishes.

After his interesting experience (see Part 1, p. 175) Jobert (1898) collected at Pará in 1877 some of the lesser candirús by the turtle-shell method, and took them to the Museum d'Histoire Naturelle in Paris. In 1911 Pellegrin examined these specimens and found them to be *Stegophilus insidiosus*, the very fish of which Reinhardt wrote so interestingly in 1859, and an undoubted blood-sucking parasite. It is shown herein as Figures 6, 7 and 8.

Next to be referred to is Pellegrin himself (1909a, 1909b, and 1911) who goes thoroughly into the structures of *Vandellia wieneri* (Figs. 9 and 10) and finds it a parasite. He analyzes the candirú stories and while he does not say that his fish is a candirú, it is plain that it is. And last comes Le Cointe (1922) who like the first candirú narrator (Martius, 1829) erroneously thinks that the fish is a *Cetopsis*. On this point see the quotation from Dr. da Matta (above). Unfortunately Le Cointe gives no figure.

Haseman, whose collecting experience (as noted previously) was most extensive, merely makes the general statement (1911a) that various species of pygidiids are given the colloquial name candirú. But Hase-

man's teacher, Eigenmann, in his great monograph on these fishes has gone more fully than any previous writer into the matter of what fishes are named candirú. He finds that, excepting the genus *Nemato-genys* with one species, all the Pygidiidae are long slender fishes, and all have the opercle and interopercle beset with patches of spines. Further he finds in addition that all the members of the sub-families Vandellinae and Stegophilinae have the mouth inferior and the gill-openings restricted. These structures, their light (even white) color, and the known facts of their habits lead Eigenmann (1918b, p. 277) to speak of the "parasitic Stegophilinae and the urinophilous Vandellinae."

Probably all the fishes called candirú by the riverines are to be found in these two sub-families only, and of the genera and species in these we may strongly suspect that *Acanthopoma annectens*, *Stegophilus insidiosus*, and the five species of *Vandellia* (especially *cirrhusa*, *wieneri* and *sanguinea*) are the fishes called candirú by the dwellers on the Amazon. *Branchoica bertonii* is also an undoubted endoparasite, but so far as now known is not found in Amazonian waters where the candirú seems most to abound. That there is here a most interesting field for study, is clear to the reader.

IS THE CANDIRÚ URINOPHILOUS?

This is a question that must in the final analysis be answered by experiment. But leaving for consideration in the next section the question of whether or not the alleged penetration of the urethra results from a tropism to urine or from the instinct to hide, the scanty evidence will now be presented as to urinophilism.

Martius (1829 and 1831) says that "these little fish are strangely attracted by the odor of urine." Next Schomburgk (1840) was told that penetration is especially likely to take place if urine is passed while bathing. Castelnau's statement (1855) is more direct. He says that the fishermen of the Araguay "claim that it is dangerous to urinate into the river,

because this little animal [*Trichomycterus pusillus*] springs out of the water and penetrates into the urethra by ascending the length of the liquid column." His words are "d'uriner dans la rivière." Whether *dans* should be translated *in* or *into*, indicating whether the body at the time is submerged or not, is determined by the context as given above.

Castelnau uses the word *prétendent*, and this may be translated claim, allege or pretend. At any rate he seemed to have had doubts and as the statement stands it is of course absolutely preposterous. However, there may be something to it after all. In discussing my paper with Mr. C. M. Breder, Jr., of the New York Aquarium, he told me that while collecting fishes in the Rio Chucunaque in Panama in 1924, he made the interesting observation that if any one stood on the bank and urinated into the stream swarms of *Astyanax ruberrimus*, a small characin fish averaging 3 to 5 inches in length, would collect and "would apparently try to ascend the stream of urine." Because of this tropism for urine, it was considered unwise to micturate while in bathing.

Tallying exactly with Breder and backing up Castelnau in general is the testimony of Dr. Charles C. Ammerman, a naval surgeon, who on the Madeira River in 1910-11 became quite well acquainted with the candirú. Prof. E. C. Starks; the distinguished ichthyologist of Stanford University, while studying fishes in the Philippines in 1926, met Dr. Ammerman and told him of my work on this fish. Dr. Ammerman then said that it was the belief on the river that the fish entered the urethra or vagina only when urine was passed while in the water. Prof. Starks wrote me that: "He said that if one urinated into the water, these fishes would come to the top and act as if crazy for the urine, the salt water."

These are the facts, the interpretation of them is another matter. Three possible explanations occur to me; that these fishes are tropic to urine, that they were

merely reacting to the current of water and would have so responded if water from the same stream had been poured out of a bucket or tea-kettle, and third that they were attracted by the noise. This will be returned to later when all the evidence has been presented, but only experiment can absolutely settle the question.

Several of the other authors cited in the first section of this paper indicate that penetration takes place while bathing *if urine is voided*. So writes Marcoy (1869), while Boulenger (presumably on the authority of Dr. Bach) says that "the fish is attracted by the urine," and Jobert was informed by his Paraense friends and by his Indians that the smaller candirú was definitely urinophilous, and this was affirmed by Dr. Castro. And von Ihering (1914) states positively that the candirú is urinophilous. The other writers quoted in the first section of this paper do not state the matter as specifically as do those mentioned, but one plainly gets the idea that all believe the fish to be urinophilous.

Eigenmann in his great monograph (1918b) speaks of "the urinophilous *Vandellinae*" (p. 277), and his remarks on the habits of the fishes of this family plainly indicate his belief in this particular habit. Later in his paper he establishes the inclusive genus *Urinophilus* to replace the old genus *Vandellia* with 5 species. In 1922, he names a new species of pygidiid, *Urinophilus erythrurus*, from the head waters of the Amazon. From all this it is clear that Eigenmann, the authority on these fishes, believed certain ones to be urinophilous.

So far as I know but one man has actually experimented to determine the fact. Allen (1921) writes that:

An effort was made by the expedition to confirm the widespread reputation of the candirú (carnero of Peru). A Briggs lead-in trap properly baited was frequently placed in rivers in the hope that it might demonstrate such a tropism. This was never successful.

Seeking for details of this baiting, I wrote Professor Allen suggesting that to make an absolute test of the matter it would be necessary to have a reservoir of urine discharging into the trap a steady stream, and that this urine would have to flow out of the mouth of the trap with the current, and so attract fishes facing upstream. He kindly answered that: "I merely saturated with urine rather tightly rolled pledglets of cotton and cheesecloth. These were used for bait. It may not have been as good a method as a steadily feeding reservoir of urine, but I believe that it should have answered the purpose." Whether or not candirús are known to abound in the streams where the traps were set is not stated. Certainly there is in this matter an interesting field for further experiment.

An interesting sidelight on this matter is to be found in a continuation of Mr. Breder's observations on the habits of the small characins of the Rio Chucunaque of Panama. After saying that the Indians of these parts for sanitary purposes make use of the flowing streams as sewers, and that these fishes are attracted by and feed upon human feces, he states that they are markedly attracted by flesh and blood and by human secretions in general. Specifically he added that: "*In this connection Astyanax ruberrimus* [the small characin referred to above was noticeably attracted to the crotch and armpits of swimmers and bathers, by the abundant perspiration given off there. Here these little fishes would bite at the hairs until the men had been in the water for some time. Then when these secretions had been washed away these localized regions no longer possessed superior attractions and the little fishes distributed their tiny attacks over the whole body, particularly where there were warts, calluses, or clumps of hair on which they could lay hold." This is in accord with Martius (1831) who says: "The odor of men's secretions [he uses the plural] appears to attract the little fish."

Now it has clearly been shown above that the more specialized pygidiids are attracted by flesh and blood, that they will attack and scarify not merely the gills but the bodies of fishes, that they will attack the bodies of mammalian beasts, and that they will puncture the skin and suck the blood of man, as has been noted by Poeppig (1836), Jobert (1898) and by Haseman (1911a and b). They must be attracted to these animals, particularly to man, by the odorous secretions given off by the body. Nor does it seem too much to think that they would be attracted by the most abundant and possibly the most tropic of all, urine.

In answer to the question: Is the candirú, a pygidiid catfish, urinophilous? one must counter with the Scotch verdict: Not proven! However it seems to me that the evidence as set forth seems strongly to indicate that the candirús are tropic to urine. Additional facts to be presented in the next section also favor this conclusion. The data set forth with regard to the characins enables us to reason from analogy (a rather dangerous thing unless carefully safeguarded) but it should be stated that the characins are tropical freshwater fishes, are found in the Amazon and its tributaries, and along with the family Pygidiidae belong to the same sub-order, i.e. are fairly closely related.

DOES THE CANDIRÚ ENTER THE HUMAN URETHRA?

During the many years in which the accounts of this alleged habit have been accumulating in my files, I have been very skeptical on the subject. In considering the data one could not so readily apply the principle of cumulative evidence extending over wide regions and long periods of time, the principle made use of in my previous articles on "Rains of Fishes"¹ where the timespan was 1600 years and the region covered extended continuously from Scotland across Europe and

Asia to the South Sea Islands, with North and South America, and Africa also included.

In the present case our time span extends only from 1829 to the present day, an even 100 years. The regional distribution is likewise confined to the Amazon and its tributaries. The peoples too instead of being of diverse races are the mixed, but as such fairly homogeneous, riverine population of Amazonas, uneducated, superstitious, given to recitals of the marvellous, ready to credit the incredible. This recital shows my mental attitude on beginning the study of my materials. While these matters were being turned over in my mind I was working through the great catalogue of the Surgeon General's Library in search for further references on this subject, with the following results.

In the medical literature there are found scattering references to the penetration of the human urethra by leeches and insect larvae, and a considerable number of citations to accounts of the voiding with the urine of insects and their larvae and of worms. Without going into any discussion of the various ways in which these animate things gained entrance to the bladder and urinary passages, it may be conjectured that for the most part they penetrated and ascended the urethra and in the bladder laid their eggs which afterwards hatched and as larvae or imagos came out through the same urethra. One case of penetration by fishes was also noted: Jobert's, previously cited. Of the invertebrate penetrations and voidings it is interesting to note that 74 cases are specifically listed in this catalogue.

From this it is seen that certain elongate and sinuous invertebrates do penetrate the human urethra, but the persistent question is: Do the elongate and sinuous candirús do so?

In the first section of this paper all the known accounts, mainly from the writings of scientific men and of travellers

¹ *Natural History*, 607-619, 1921; and *Ann. & Mag. Natural History*, s. 10, 3: 1-26, 1920, pl. 2 text-figs.

of reputable standing, are brought together in chronological order and, on the principle that where there is so much smoke there must be some fire, they cannot be cast aside as impossible and worthless, even though individual accounts (as Lange's) are plainly not to be accepted. Let the interested reader turn to the first section and again peruse the statements made, and he will then be prepared for the evidence and argument to be set out in the next following paragraphs. This evidence is of two kinds, and the first has to do with means used to prevent the entrance of the fish.

Precautions against Entrance. Martius (1829) says that before going into the water the riverines constrict (tie) the prepuce with a string. Jobert (1898) had not been a day in Pará in 1877 when he was urged to follow the practice of the Tapuyo Indians and to wear the protective ligature. Later when he saw his Indian fishermen apply this and when he realized how uncomfortable it was he realized that these men absolutely believed in the phenomenon of penetration.

In his second account (1831), Martius represents the riverines as advising that "the organ be covered carefully" but gives no description of the protecting device. At the meeting of the Zoological Society of London previously referred to, Boulenger (1898a), in presenting the data on the habits of the candirú collected and sent to him by Dr. Bach from the Rio Jurua, states that the natives of this region "... rarely enter the river without covering their genitalia by means of a sheath formed of a small coconut shell, with a minute perforation to let out the urine, maintained in a sort of bag of palm fibres suspended from a belt of the same materials." Dr. Bach to make the matter clear sent to Boulenger a photograph showing two otherwise naked Indians wearing the device, but apparently did not send the device itself.

Hoping that the photograph in question was on file in the British Museum (Natural

History), I wrote Mr. J. R. Norman of the department of fishes for information and if possible for a copy. Being unable to find it he wrote Dr. Boulenger, who is now living in Belgium. Dr. Boulenger answered that "So far as I can recollect after so many years the photographs . . . were the property of the Brazilian Doctor [Bach] on whose behalf they were exhibited and were returned to him." It is greatly to be regretted that these photographs were not published and thus put visibly on record.

Corroboratory of Bach's description Prof. E. C. Starks of Stanford University writes me that he has seen a photograph of such a protective device. This photograph he thinks was brought from Brazil by the late Prof. J. C. Branner, who did much exploratory work in Brazil and knew much of the habits of the people. Search has been made through Dr. Branner's photographs but unfortunately the desired picture has not been found.

There are now to be set forth certain facts, the connection of which with the matter under discussion is not wholly clear in my mind. However, there is a strong possibility that if these matters were worked out in Brazil by a competent ethnologist, they might throw a flood of light on the subject. Hence it seems advisable to set them down.

The first of these is to be found in the book (1886) of the ethnologist, Steinen, previously referred to. On page 239 in a footnote there is a description of a penis sheath worn by the Yuruna Indians on the lower Xingu, a tributary of the lower Amazon. This is cone shaped, is cut off horizontally above and obliquely below, is made of strips of dried palm leaves, and in size is about equal to the length and diameter of the two lower phalanges of the smallest digit. This presses the corpora cavernosa back into the scrotum and causes this to swell out tumor-like. Thus the penis is entirely and the scrotum partly covered by this sheath. Earlier (p. 178) and higher up the river. Steinen had

remarked on the danger to bathers of the candirú, but here as to the purpose of this sheath he says "Atque cum urethra

men also wear a sheath. That worn on festive occasions is shown in his Figure 132, and has a flag-like appendage. This

FIG. 14. *Penisstulp* worn by men of Baroró tribe on headwaters of Xingu River. It is called *Inobá* by Indians and *Gravatá* by Brazilians. Figure is $\frac{3}{5}$ natural size. (After Steinen, 1897.)

prorsus conclusa sit, insecta intrare non possunt." This has puzzled me very much, but apparently it refers to such a matter as that referred to in the paragraph relating to citations in the Catalogue of the Surgeon General's Library.

However, the matter was somewhat cleared up when I got Steinen's second book (1897) describing a second journey in 1887-88 to the headwaters of the Xingu. In this he goes carefully into the ethnology of the tribes of this region. He does not refer to the candirú, but he does figure and describe certain devices for covering the pudenda which seem to have some bearing on our subject.

My attention was first called to the fact that in his Figures 137 and 144 men are represented with the foreskin tied over the glans. Reference to the text showed that this ligature was applied to boys on their reaching puberty. The very idiomatic language of the text is hard to translate but it is clear that the

FIG. 15. *Uluri* or pudendal covering worn by Bakairi women on headwaters of Xingu River. (After Steinen, 1897.)

sheath is made of strips of dried palm leaves. The prepuce is drawn through the open point of the sheath which constricts it just as the ligature does. This is shown herein as Figure 14 and is called *Inobá* or in Brazilian *Gravatá*.

Next I noticed in his Figures 6 and 31 women also shown wearing a protective device. This is portrayed in detail in his Figure 43, reproduced herein as Figure 15. This object, called *Uluri*, is made of bark folded and tied as shown and is worn as shown in place in the smaller figure. Both this device and that worn by the men are very uncomfortable but seem to be *de rigueur*.

Krause, also a trained ethnologist, led an expedition in 1908, into the valley of the Araguana River, a tributary of the Tocantins lying between that river and the Xingu, whose inhabitants (as

will be seen) have the same general habits as those of the latter river. Inspection of the numerous figures in his book

FIG. 16. Lateral and underside views of *Penisstulp* (*Imudje*) worn by men of Kanapó and Tapirapé tribes along Araguana River. (After Krause, 1911.)

(1911) showed the same ligated prepuces as portrayed by Steinen. Among the Karajá, the assumption of the penis string marks the age of puberty. This was also true of the Savajé. Some of the Karajá men also wear a penis sheath. On the other hand among the Kanapó the penis sheath is assumed at puberty. This, called *Imudje*, as shown in Figure 16 (his Fig. 217a and b), is very like that figured by Steinen as worn by the Bororó. This is drawn over the penis with the foreskin pulled forward and constricted as in the case of the Bororó also. This sheath is woven of strips of palm leaf, both by the Kanapó and the Tapirapé.¹

Madame Snethlage of the Museu Goeldi (Museu Paraense) of Pará in 1913 published an account of an exploratory journey up a tributary of the Xingu and down another of the Tapajos. In the course of this trip she met many Indian men wearing the penis sheath. Her photographs show men of two tribes thus attired. Nowhere in her (Portuguese) text do I find any specific references to the plates, hence I have been unable to have any

¹ These proper names designate certain tribes living in the valleys of the Zingu and Araguana.

translations made of any descriptions of these objects. The objects themselves, shown in the half tones of groups of men, are so small and so poorly represented that it is impossible to reproduce them here.

What the connection may be between the constrictive ligature and the sheath worn by the tribes in these two river basins seemingly as a matter of tribal custom or as clothing, and the same devices worn throughout the rest of Amazonas as a protection against the candirú, is not wholly clear. The candirú is known and feared on both the Araguana and the Xingu but none of the explorers mentioned in this article speak of the use of these devices as protection against its attacks.

Now since tying the penis or wearing a sheath is a widespread custom among primitive peoples the world over, then why is it not widespread among the aborigines of South America? So, acting on the statement of Steinen (1897, p. 359) that "the sheath was formerly widely used throughout Brasil," I made a search with the following interesting results. Nordenskiöld (1924) briefly in his text refers to this matter, but, what is more to our purpose here, tabulates the data known to him as follows, giving references to the authorities: 26 South American tribes are known to use a penis cover, 12 to tie this organ up to a waist band, 9 to constrict the prepuce with a thread or string, 19 to use a "lap" (the "apron" presently to be referred to by Bancroft). Nordenskiöld's map shows these methods to be widely and fairly uniformly diffused over the whole of South America north of the tropic of Capricorn, but the symbols showing where the various practices are found are especially thick in Amazonas and the Guianas.

What the connection is in the use of these devices and the use of those against the candirú is not clear, but there seemingly is such. It may be conjectured that those aborigines living along the navigable waterways, and who have come in contact

with the whites, have been lead to leave off these devices which certainly are uncomfortable, and to put on the white man's clothing. However, many of them have, to the present time when going in the rivers, continued to wear the ligature or the pudendal covering as a protection against the candirús, and, in the case of the sheath, possibly against the piranhas also. However, this is a conjecture only, the matter is one for the ethnologists.

My attention has been called to Blanchard (1904) who in a short note refers to the candirú (in which he alleges disbelief) and to the use throughout Amazonas of the protective device on the penis when in the river. Then he adds:

A similar belief and a similar practice occur in South Africa, where haematuria due to *Bilbarzia* is found. It is acknowledged that this disease is caused by a parasite which lives in the water and penetrates the urethra of bathers. These natives too have the custom of covering the glans or binding the penis when they enter the water.

We figure here the protective covering used by the Zulus of Rhodesia. This interesting object, very easy to weave, has recently been brought from Buluwayo.

Figure 17 herein is a reproduction of this curious and interesting object. The American Museum has in its ethnological collections a number of these devices from Barotseland (two lie before me as I write) agreeing closely in their general makeup with that figured and undoubtedly used for the same purpose. It is unfortunate that in none of the large number of books of exploration on the Amazon that I have read, is any such object figured. Furthermore, application to the authorities of the Museu Nacional, Rio de Janeiro, for a photograph of this device, has failed to bring any information.

Finally, it is interesting here to note that, in these two far distant and absolutely unrelated regions, we have an excellent illustration of the saying of Alexander von Humboldt that different peoples in distant

countries under stress of similar necessities devise similar apparatuses or processes to attain similar ends.

FIG. 17. Protective device against penetration by parasitic trematode (*Bilbarzia*) worn by Zulus of Rhodesia. (After Blanchard, 1904.)

ACCOUNTS OF PENETRATION BY THE CANDIRÚ WITH METHODS OF RELIEF

Over and above the data already set forth, valuable as they are, the great desiderata for establishing the fact of the penetration of the human urethra by the candirú are eyewitness accounts by scientifically trained men and especially by medical men. From the mass of data set forth previously, these men and their statements will now be abstracted.

Martius (1831) says that through "Dr. Lacerda [in Pará] we as eyewitnesses were made cognizant of the truth of the matter." The German has been translated literally but is not clear. The point has been discussed elsewhere, but it is certain that Lacerda believed in the phenomenon and had presumably seen a case. Whether Spix and Martius were actual or figurative eyewitnesses it would seem that they gave full credence to Lacerda's account.

On the issue in question Poeppig of Leipzig University says that Spix and Martius were "very skeptical until the

well-known naturalist and physician of Pará, Dr. Lacerda, had explained its foundation in truth." Poeppig then adds, and his direct testimony cannot be disregarded:

In Yurimaguas, I myself have been an eye-witness of such a case. An Indian woman, after the penetration by a *Canero* into the vagina suffered such frightful pain and loss of blood that she was given up to die. However, after inward and outward application of [the juice of the plant called] *Xagua*, the little fish was gotten out and the woman came through alive.

We now come to Boulenger's contribution (1898a). He had his fishes and account from Dr. Bach on the Rio Jurua (upper Amazonas). Bach had not performed the amputation of the penis, which by the testimony of nearly all writers is the only thing to be done, but he had examined an Indian man and three boys, who had been so operated on. It must be noted just here that he sent to Boulenger a photograph made by himself showing the protective device in place. From this it must be concluded that Dr. Bach believed in the penetration and the resulting operation.

However, another explanation of this matter of amputation is not only possible but also probable, and in fairness digression must be made here in order to set this forth. Reference has been made to the fact that in the same waters with the candirús there are found those active, voracious and dangerous characin fishes, the piranhas and perais. As to the habits of certain of these fishes which he calls *peri* [*perai*?] let us hear that accurate observer, Edward Bancroft (1769):

It is extremely voracious, and bites everything which hangs in the water. The feet of ducks swimming in the creeks are frequently amputated; as have been the breasts of women and the privities of men swimming in the rivers; for this reason the White Inhabitants never bathe themselves in the upper parts of these rivers without tying a napkin or handkerchief about the waist.

In this account we have two matters which plainly tie up with Dr. Bach's account as given by Boulenger; first the amputation of the penis and second the covering of the pudenda with "a napkin or handkerchief" on going into the waters of Guiana. In the rivers of this region candirús have not been found so far as can be ascertained by a diligent search through the literature. Furthermore I am corroborated in this by Mr. John Tee-Van, to whose work in British Guiana reference has already been made. He has worked on the fishes of that region, and is thoroughly conversant with the literature of Guiana fishes. In this matter he has made inquiry of the Surgeon General of British Guiana, who writes that in the medical records of the colony there is no account of the candirú.

However, the books abound in accounts of mutilations by piranhas and similar stories have been communicated to me in letters from men who have explored in tropical South America, and in all these there is no lack of recitals of amputations of fingers and toes by these voracious fishes. Furthermore, Mr. Breder has personally related to me that while in Panama on the collecting trip previously referred to little characins would collect around the men hauling the seine and would nibble at their fingers, their breasts, warts, moles, or any slight projections of the skin. They were too small to do any particular damage, only occasionally drawing blood, but they showed the characteristic traits of these carnivorous fishes. These small characins were perfectly fearless in attacking men in the water but were very wary when an effort was made to enclose them in a net.

Dr. A. Hamilton Rice of New York City, an Amazonian explorer of long experience and wide knowledge, has kindly communicated to me incidents of the voracious habits of the piranhas of which he has personal knowledge. Omitting the scores of heresay accounts for which he could not personally vouch, he states

that: "I have seen most deplorable results of mutilation by the piranha, and my own men have from time to time suffered from attacks of these fish." Of the fish itself he writes: "The piranha is a voracious blood-thirsty fish of a foot to 20 inches in length, not unlike a tautog in conformation, and with jaws similar to a circular saw in power and sharpness." He notes that it is so fierce and fearless that it will leap nearly a foot out of the water to attack a man. Omitting all accounts of mutilations by it other than that of the penis, he states that he knew of a man whose organ was thus amputated and who died of the resulting hemorrhage. Of another case we will quote his own words:

In May, 1920, at the Portuguese Beneficente Hospital in Manaus, I saw a boy of ten or eleven years of age whose entire penis had been snipped off. He had been in bathing in a river at a spot where the water reached only to his knees. A piranha jumped suddenly, seized his penis, amputating it at the base.

Along the same line Dr. Alfredo da Matta of Manaus kindly writes me that among other cases of accidents by piranhas treated by him was that of a boy who had part of the corpus cavernosus of the penis torn away by one of these fierce fishes.

With this possible explanation of the matter of amputation, we will now return to the question of penetration by the fish, in order to present the remainder of the evidence. In the discussion which followed Boulenger's presentation of Dr. Bach's data, the point was evidently raised as to whether the fish was small enough and the human urethra large enough for such penetration to be possible. This query was met by Boulenger (1898b) in the following note read at the next meeting of the society:

In order that I might satisfy myself as to the possibility of the small fish, *Vandellia cirrhosa*, penetrating into the human urethra, Prof. C. Stewart kindly took me to St. Thomas's Hospital . . . when I was able to introduce without difficulty a No. 12 catheter,

5½ mm. in diameter, into the urethra of a male subject lying for post-mortem examination. The calibre of the fish being only 3 to 4 mm. no doubt can be raised as to its ability to enter the orifice of the urethra in the manner that has been described by various travellers in Brazil.

In this connection it is of interest to examine Cuvier and Valenciennes' figure of their fish which they state was "deux pouces neuf lignes" (2.75 in.) long. An outline drawing of their figure is shown herein in *natural size* (Fig. 4). Eigenmann examined two specimens of *V. cirrhosa* measuring 94 mm. (3.75 in.) and 40 mm. (1.6 in.) respectively. The smaller of these could certainly penetrate the human urethra.

Jobert (1898) thus quotes Dr. Castro of Pará, whom he describes as "a physician of high standing and a man much interested in natural history," as saying:

I firmly believe in the possibility of such an accident because I have myself extracted from the urethra of a negress a little candirú which had penetrated during micturation while bathing in the river. The patient experienced cruel suffering for, since I had to drag the animal out, the mucous membrane was lacerated and the extraction was difficult.

Another eyewitness is Le Cointe (1922), who after discussing the danger of the penetration of the urethra by the fish says: "I have personally known already three cases of this curious accident."

Le Cointe's book is based on first hand knowledge of the natural history of Amazonas. Furthermore when I was beginning in 1925 to put into definite shape the data for this article, the well-known entomologist, Dr. Joseph Bequaert of the Harvard School of Tropical Medicine returned from an expedition to the Amazon basin. I asked him if he knew anything of the candirú, and he referred me to Le Cointe's book. He said that Le Cointe had had thirty-five years' experience in the study of the fauna of the Amazon valley, and that full credence could be given to his book. He further suggested

that I write Le Cointe for details of his experience with the candirú. This I have done, and have permission to quote from his letter as follows:

During my very long sojourn in Amazonia (since 1891) I have been able to satisfy myself that . . . the candirú is really able to penetrate into the anal or vaginal cavities of men or women bathers. Its introduction into the vagina is the most frequent phenomenon, appearing moreover to be always provoked by the imprudence of the victim in urinating in the water where she is bathing.

At the time of occurrence of one of the three accidents of this kind of which I have had full cognizance, it was incumbent on me to become a party in the matter. The thing happened on the upper Beni (in Bolivia). An Indian woman, belonging to a party engaged in the exploitation of rubber which I was directing at that time (1891), took her bath in the river and feeling herself wounded tried to extract with her hand the candirú which had already penetrated almost entirely into the vaginal cavity and which spreading out its fins [gill-covers] armed with pointed spines resisted all her efforts, wounding her profoundly. Then they brought to me this woman who was bleeding profusely. Quickly recognizing what the trouble was it was necessary for me to push the candirú forward in order to disengage the spines driven into the flesh, then to turn it in order to bring the head to the front. It goes without saying that such an operation, performed without appropriate instruments, provoked a violent hemorrhage. The Indian woman suffered greatly but she had the good fortune to recover completely in a month.¹

A letter sent last year (1929) asking Le Cointe if any further data on the fish had come to his attention brought the word that there had not. However he passed my inquiry on to Dr. Americo

Campos, a practicing physician in Pará and a professor in the medical school there. Dr. Campos, who had lived for a long time in Abydos on the lower Amazon, writes as follows:

I have made no personal observations on the subject of accidents caused by the "Candirú." A lady whom I knew at Obidos, Dona J. S., told me that a candirú entered her vagina and that it was necessary to call in a doctor to get it out. At Obidos, Santarem, and Alenquer I have heard various instances spoken of where the candirú has penetrated the ear, the nose, the anus. It is a fact that this supposition and this fear are common in the localities cited above.

Professor Starks has communicated to me the further testimony of Dr. Ammerman (the U. S. naval surgeon quoted on p. 445) on this matter of penetration. I have been unable to get in touch with Dr. Ammerman, and so have here to quote from Professor Starks' letter.

Dr. Ammerman said that he had spent considerable time in 1910-11 on the Madeira River. I asked about the candirú and he answered that he had operated for it two or three times . . . In one instance he tried to pull a fish out of a patient's penis but the tail pulled off and he had to operate, making a supra-pubic opening into the bladder to remove the fish which had penetrated into that organ.

Finally I am privileged to quote from Dr. Alfredo da Matta of Manaus, who has been referred to previously. He writes that the candirús are well known in his region, living along inhabited shores, in clear ("white water") streams (i.e. the Amazon, etc.), but are found less abundantly in "dark or clouded water" ("black water" streams), the Rio Negro and others. They are greatly attracted by blood. "For this reason they attack women who are menstruating, during the catamenial period, when they are washing their clothes." He then gives me the following account of a case in his own practice:

Two cases of accidents due to candirús are as follows. The first concerns a girl who, while

¹ It may not be out of place here to add two other methods of treatment for the candirú. Marcoy (1869) says that the 'native' Ucayali doctors know of but one remedy, which consists of a *tisane* made with the *genipa* or *buitach* apple, and which taken very hot acts, they pretend, on the urinary passages and dissolves the animal which obstructs them. And as to treatment Steinen (1884) simply says that "If a hot bath does not bring the disturber out, then the only thing left is an operation," i.e. amputation in the case of a male.

menstruating, went naked to bathe herself in the Cambixe, Rio Solimões. The girls were in the habit of staying quietly in rather shallow water, only their heads out of water, and thus bathing themselves. This is what she was doing. The candirú introduced itself part way into the vagina, causing a hemorrhage when it was pulled out, and a subsequent severe inflammation. This operation requires some caution and skill because if, in order to withdraw it, the candirú is caught by its tail or by its body it expands its dorsal and ventral spines into the tissues, which fix it there more firmly than ever. The girl had to stay in bed some days.

The other case was told me. It was that a candirú had introduced its cephalic parts into the urinary meatus of a fisherman who, naked, was working in the water in the Rio Solimões, at Boa Vista. This was pulled out without difficulty or danger. Other accidents are told of, but I do not have entire confidence in them.

Here then is the evidence of actual experience by a modernly trained, scientifically minded physician, whose word cannot be doubted. However, before "summing up," as a lawyer does his case, it will be of interest to note in what relative numbers men and women have been recorded as attacked by the candirú. Most of the accounts do not distinguish sexes, but a few do. Bach's report through Boulenger (1898) was that on the upper Jurua he had seen one man and three boys with amputated penes, but the absolute reason and method of amputation is not specified, and it is at least conjectural that this may have been done by piranhas. For attacks on women we have better evidence. Poeppig (1836) personally witnessed such an accident. Castro told Jobert of numerous cases (probably hearsay accounts) in the Amazon basin, but personally operated on one woman. Le Cointe says that both men and women are attacked, the latter more frequently, and in his letter describes his operation on a woman.

So much for the published accounts. The data now to be given has come in personal letters to the present writer and

is quoted by permission of the writers. Dr. da Matta has just been quoted for both sexes, but indicates that women are most subject to such attacks.

Professor Allen of the University of Kentucky writes that: "The Peruvians have a larger fish, which they say attacks women. I found the Peruvian men rarely entering the river, the women never. This was more due to fear of the *carnero* (candirú) than the *pañá*—*piranha* of Brazil." This account is corroborated by Mr. W. K. Pearson of Indiana University who writes of the Rio Beni (one of the headwaters of the Amazon) that: "None of these [candirú] stories related to attacks on males. The female is apparently the only one attacked in this region. It is certain that anything but the very young of the *Urinophilus erythrus* would be too large to enter the urethra of a man." On p. 178 Mr. Pearson is quoted for a hearsay but very vivid account of such a penetration in the case of a woman.

The preponderance of accounts of the penetration by the candirú in women over men has of course its explanation based on the comparative anatomy of the genitourinary organs in the two sexes. In men the orifice is open at micturition, and then very narrowly. In women in bathing or sitting in the water washing clothes the vulva is apt to be open and the vagina being a much larger orifice than the urethra, penetration of this is comparatively easy.

In this connection the observations of Breder on the small characins of the Rio Chucunaque, Panama, cast an interesting sidelight on the phenomenon in question. Account has already been given elsewhere of the fearlessness of these little fishes and of their ferocious attacks on moles, warts, nipples, calluses, and tufts of hairs of persons in the water. The Indians defecate in the streams, wading out into water up to their waists, or squatting down until the water reaches the waist line. Around such persons the little fishes collect in swarms, making

tiny attacks on every projecting part of the body. The genitalia of the women are particularly attacked and it would seem that this would be unbearable but the stolid Indian women seem to pay no attention to it. Let the places of the characins be taken by the equally small and carnivorous but also secretive and urinophilous candirús and the seeking of a hiding place in the vagina would easily follow.

In working up this data, it has forcibly struck me that no cases of penetration of the rectum are on record. One would think that the candirú in seeking a recess to creep into would not overlook such an orifice as this even though more or less closed. This matter may, it is true, negatively indicate urinotropism. Most of the writers quoted speak of penetration of the secret openings of the body, speaking almost invariably in the plural. However, Schomburgk speaks specifically of alleged penetration of the rectum, and Le Cointe says that it penetrates the anal opening, as does Dr. Campos also.

Again there are no records known to me of the candirú's having penetrated the urinary passages of such large fishes as the Pirarucu and the huge catfishes of the Amazon, or the urethra and bladder of alligators and turtles among reptiles, of the dolphin and the manatee among water mammals, and of the terrestrial tapir and domestic cattle and horses when bathing in the river. However, in explanation it may be said that we have no accounts of such dissections of these animals as would reveal the presence of the candirú. There is certainly an opportunity here for interesting research.

From the data set forth and carefully analyzed in the preceding pages, the reader must make up his own mind as to the credibility of the widespread belief in the Amazon basin of the penetration of the human urethra by the candirú, a slender catfish of those waters, of secretive habits, having patches of hooks on the gill-covers and the back of the head, a suctorial

mouth on the under side beset with rasping teeth, having much restricted branchial openings and a short straight stomach and intestine: all these things fitting it for holding fast, rasping the skin, and sucking the blood of its host. On the bare face of the matter it seems absolutely incredible, but so does many another matter, either in ichthyology or medicine, to which our minds are not accustomed. As Prof. W. K. Brooks of the Johns Hopkins University used to say to his students: "It is not safe to say that a thing, no matter how improbable it may seem to you, does not exist because you have never seen it."

There is herein set forth a great mass of testimony bearing on the phenomenon from 1829 to 1929, and the very mass of this testimony backed by the names of the testifiers is impressive. In 1831 Dr. Lacerda, a physician of high standing in Pará, a friend of Spix and Martius, made it as clear to them as if they "were eyewitnesses." The positive eyewitness testimony of Professor Poeppig of Leipzig University is prime evidence. Dr. Bach was evidently sincere in his testimony, which seemingly convinced Boulenger. Jobert testifies to the high standing in Pará of Dr. Castro, who asserts that he operated on a case of penetration. Next we have Le Cointe, who says that he has known personally three cases of penetration and who describes one operation which he performed. Dr. Ammerman testifies that he operated for candirús two or three times, once extracting the fish from the patient's bladder. There are the accounts mentioned by Dr. Campos of the medical school at Pará, to which he evidently gave some credence since he was kind enough to transmit them. And finally there is the testimony of Dr. da Matta of Manóas of a case in his own practice.

It seems to me that this evidence is sufficient to convince a jury in a court of law, and I cannot withhold my belief in it.

BOOK REVIEWS

THE PHYSICIAN THROUGHOUT THE AGES. By Arthur Selwyn-Brown. N. Y., Capehart Brown Co., 1928.

For the publication of these two massive volumes little excuse is to be found. The foreword is preceded by a picture of the Editor and followed by James Whitcomb Riley's poem "The Doctor." Chapter 1 is headed "Primitive Medicine and the Medical Man; Antiquity and Universality of Disease; Paleopathology Supplies Interesting Evidence" and from there on scissors and paste are used to fill two volumes of over 800 pages each, 12 by 9 inches, double column. Articles are duly credited to their authors but not always to the place of original publication. It is not quite clear for whom this work is intended. Many of the pages read like the daily tabloids, others are fairly scientific. If the idea was to present a complete history of medicine, either popular or scientific, then it may be said that this has been much better done in many other volumes. Taking the books at random we find Chap. xvi in Volume 1 on "Rise of the Medical Libraries, Foundation of Scientific Biology" and we see a black-face headline reading "Alexandrine Libraries Exert Vast Influence," followed by this illuminating paragraph: "The libraries played a great part in diffusing medical and scientific knowledge, and none appears to have exerted more influence than the great library at Alexandria." Other headlines read "Aristotle Skilled in Dissection" and "Aristotle, the First Scientific Biologist." Opening Volume II at random we come to Chapter xli headed "Death and its Significance, Immortality Revealed by Anesthesia," a headline that must be the envy of the editor of every sensational newspaper. We also find such headings as "Fear of Death is Baseless" and are suddenly confronted with a portrait with the caption "Julius Wagner-Jauregg, M.D., Noble Prize Man (*sic!*) in Medicine, 1927." Another heading reads "Fatalism, Irony, and Charity" and right after this we find "The Biology of Death" by Raymond Pearl, M.D. A book of surprises if there ever was one! Book ix has the title "The Doctor as an Adventurer in Literature and the

Arts: A Galaxy of Able Writers" and here is reprinted "Man's Redemption of Man: An Inspiring Essay, by William Osler, M.D." No reference to previous publication or permission to republish is made. It would have seemed good taste to mention its earlier publication and not to create any possible impression of its being written for this work which was published nine years after Sir William's death. In the following pages are such headlines as "True Until Death," "Professor Coue Anticipated," "Were the Mules Responsible?," "A Mental Teaser." There is much more that is amusing and even irritating in these volumes.

There is also a little wheat among great quantities of chaff. The bibliography on page 812 contains the following paragraph: "This bibliography has been compiled to guide students to sources for augmented reading. Most of the books cited contain bibliographical references which will lead to further and ultimate sources whenever more exhaustive studies are required. Unfortunately, medical history has been a neglected study and its source materials are rare and are confined to a few of the larger European libraries." This statement will probably be a surprise to those who have access to such libraries as the Surgeon General's, those of the New York Academy of Medicine, the College of Physicians in Philadelphia, the John Crerar Library in Chicago, the Boston Medical Library, to say nothing of the new William Welch Library, in Baltimore. Perhaps, however, the statement is not so surprising when it is noted that one looks in vain for the names of such modern historians as Sudhoff and Garrison, to say nothing of many others. We find the index headed "Index and Chronology of Distinguished Physicians and World-Known Authorities." This is followed by the "Index of Subjects" in which we find such citations as "Arabs Were Mentally Keen," "Bible Story Illustrated, A," "Libido, The Ego Displaces the," "Numerology Still Used in Medical Practice" (turning to this reference we find it discusses the use of numerology by the Arabs). As said before, the work has its amusing as well as irritating side and not the least of these is its price—\$25.00.

A CLINICAL STUDY OF THE ABDOMINAL CAVITY AND PERITONEUM

SECTION I. THE CAVITY (*Continued*)*

B. THE FLOOR, OR PELVIS

The Anatomical
vs. the Functional
Abdominal Floor

THE abdominal cavity, strictly speaking, has no floor for its lowest limit is simply an arbitrary anatomical boundary, the pelvic inlet or brim of the true pelvis (see Fig. 13). The interest of the surgeon is in the functional floor of the abdomen. This consists of the pelvic bones, the pelvic viscera, and that muscular sling known as the pelvic diaphragm (see Fig. 14). The contraction of this pelvic diaphragm (two pairs of thin muscles, the levatores ani and coccygei) as that of the true diaphragm, plays an important rôle in producing changes in intra-abdominal pressures and the pelvic floor supports abdominal as well as pelvic organs (see Fig. 15). The abdomen proper, then, ends as an opening or space, bounded anteriorly by the symphysis pubis and pubic crests, posteriorly by the sacral promontory and laterally by the iliopectineal lines; and the word pelvis (L. a basin), when used without qualification refers to the pelvis minor, i.e. that portion of the body cavity situated below the plane of the inlet.

The Abdominal
Surgeon and the
Pelvic Diaphragm

There are many reasons why the pelvic floor is of special interest to the abdominal surgeon. Its orifices provide avenues through which he may examine, digitally and instrumentally, the lowest regions reached by peritoneum (rectal, vaginal, sigmoidoscopic and cystoscopic examinations): discharges

* With the January, 1930 issue, p. 193 began a study of the abdominal cavity as an empty space, i.e., as simply a container for the organs upon which the abdominal surgeon must operate. The roof of the cavity, the diaphragm, was investigated and as the embryology, anatomy, and physiology of this structure were reviewed, minute consideration was given to clinical points, the interpretation of which was dependent upon peculiarities in the arrangement and function of the diaphragm.

through these orifices are important in the diagnosis of pathological conditions within the abdomen (clay-colored and frothy stools, melena, azotorrhea); reflex phenomena of

FIG. 13. Lower anatomical boundary of abdomen. Pelvic inlet.

A. Symphysis pubis. B. Pubic crest. C. Ilio-pectineal line. D. Sacral promontory. E. Ala of sacrum.

importance in abdominal differential diagnosis may be present in the region of the pelvic outlets (pruritus, spasticity; viscerosensory and visceromotor phenomena); venous congestion within the rectum (internal hemorrhoids) is often indicative of portal obstruction; infections and foreign bodies reach the abdomen through the orifices of the pelvic floor (pneumococcus and gonorrheal peritonitis; rectal foreign bodies); and the anus provides an ideal approach for the administration of fluids, food and medicines in the treatment of various intra-abdominal diseases; furthermore, the abdominal surgeon must study the anatomy and physiology of the anus and rectum to be able to create a permanent inguinal or abdominal colostomy which will perform its tasks in a manner which is adequate and satisfactory; in addition, the pelvic route may be employed for the drainage of collections of pus which have

FIG. 14. Functional floor of abdominal cavity, consisting of (1) pelvic bones, (2) pelvic viscera, (3) pelvic diaphragm. Showing lowest reflections of peritoneum. (After Weisse.)

gravitated from the abdomen to the lowest reflexions of peritoneum.

The importance of the anus for diagnosis is well expressed

Pathological Processes in the Pelvic Peritoneal Pouches

FIG. 15. Pelvic diaphragm. (After Cunningham.)

by the statements that “a finger within the rectum may yield more information than a thermometer within the mouth,” and that “the difference between the general practitioner and the surgical consultant is this: the consultant does not neglect the rectal examination”; again, by the somewhat less elegant expression that “the diagnostician who fails to put his finger into the rectum very often puts his foot in it.” By examination through the anus (*L. annus*, a ring) it is possible to detect the tenderness of acute inflammations, to locate adhesions which have fixations to the rectum, and to palpate masses located within or pressing upon the rectal walls. Within the perirectal reflexions of peritoneum (pouch of Douglas); rectovesical and lateral or pararectal pouches) there may be discovered abnormalities such as the prolapse of abdominal

organs, or local collections of blood, pus, or malignant tissue (see Fig. 16).

Reaching the Peritoneal Pouches

Due to the elasticity of the pelvic floor the surgeon may

FIG. 16. Rectal examination. Palpating rectovesical pouch. In this case a collection of pus is shown in the pouch. (From Bailey.)

reach further into the rectum than the normal 3 to 4 inches representing the length of his index finger. A slow, steady upward pressure allows considerable inversion of the pelvic diaphragm and this may carry the examining digit to a point from 1 to 1½ inches higher within the canal. The normal height of the rectovesical and rectouterine pouches varies considerably. As a rule, with empty rectum and bladder, the fold of peritoneum upon the anterior rectal wall comes to 2 or 2½ inches from the anus (1 inch or 2.5 cm. above the base of the prostate);¹⁸ i.e. opposite the level of the fifth sacral vertebra. When the rectum or bladder is distended the reflexions of peritoneum lie considerably higher and may extend well beyond the reach of the palpating finger. In a child the pelvis is shallow while the peritoneum is reflected to much lower levels than in the adult, both factors contributing to the ease with which the lower abdomen may be reached during childhood.

It is important to be both gentle and deliberate when performing a rectal examination, if most is to be gained from the procedure. The extreme distance to which the digit may be passed when the patient has been anesthetized—(whether by a general anesthetic or by spinal or caudal nerve block) illustrates the advantage in securing muscular relaxation. The patient is warned not to strain but to lie quietly, breathing with the mouth open; and is informed as to exactly when the examination is about to begin. The finger is best held firmly against the anal verge until the sphincter is felt to yield, rather than thrust forcefully into the rectum. The finger, gloved and well lubricated throughout its entire length, is introduced very slowly and with a slight rotary movement. The presence of hardened feces renders the examination unsatisfactory and if these are encountered the procedure is best deferred. The novice has at times, mistaken the uterine cervix or fundus, felt through the rectal wall, for an ulcer or a new growth. It is well, when examining the female, to identify the uterus before searching for other structures or pathological conditions. The examination should be conducted systematically, “synchronizing the mind and the finger.” Local inspection of the perianal region with the aid of a good light should be the initial step in every examination. The actual palpation may be carried out as follows:¹⁹

- | | | |
|---------------|---|--------------------------------------|

| | | |
| | | |

Having completed the examination the finger is examined for blood, mucus, or pus.

Any of the following five positions may be employed: (1) the knee-chest (or knee-elbow) (see Fig. 17); (2) the left lateral position (Sim's) (or right lateral position); (3) the

FIG. 17. Rectal examination. Knee-elbow position. (From Bailey.)

lithotomy (or exaggerated lithotomy); (4) the squatting, or (5) the dorsal decubitus. The routine position for the male is usually the knee-chest; for the female, the Sim's position; the squatting posture is reserved for instances in which a high obstruction or tumor is sought or a prolapse is being examined; the dorsal decubitus is reserved for patients who are confined to bed and are too ill to be turned upon the side, particularly those with acute peritonitis.

A rectal examination is indicated in every case of suspected intra-abdominal malignancy. Tumor cells or small masses of neoplastic tissue may become detached from any subserous malignancy and may be thrown into the peritoneal cavity, there to be carried by gravitation to the pelvic peritoneum and to form metastatic growths which may be felt upon rectal digital examination (see Fig. 18).

The sigmoidoscope makes it possible to examine still higher levels of the gastrointestinal tract by way of the pelvic floor. In passing this instrument it is necessary to bear in mind the curves which will be encountered before the abdomen

Transcelomic
Malignant Trans-
plants

Passing the Sig-
moidoscope

is reached. The rectum is not, as its name might imply, a perfectly straight tube. Inspection from the anteroposterior and also from the lateral views shows that it has curvatures

FIG. 18. Transcelomic malignant transplants, showing nodules of malignant tissue which have gravitated to the lowest portions of the peritoneal cavity and may be palpated through the rectal wall.

in both planes. The course of the terminal bowel is as follows: The pelvic colon terminates to the left of the midline; the rectum thence follows the hollow of the sacrum, while the anal canal pierces the pelvic floor in a direction which is downward and *backward*. Therefore the course of the sigmoido-

scope, which passes in the opposite direction, or from below upward, must be: first upward and *forward* through the anal canal ($1\frac{1}{2}$ in.), then upward and *backward* following the

FIG. 19. Houston's valves.

A, Lateral curvatures in rectal walls. Note that middle curve marks approximately level of lowest reflection of the peritoneum.

B, Note sacculations caused by the plicae transversals or semilunar folds of Houston.

depths of the sacral curvature; and finally, in order to clear the sacral promontory and enter the sigmoid colon (i.e. to enter the abdomen), the instrument must be so directed as to take a path which is upward, *forward*, and *to the left*. To facilitate the passage of the sigmoidoscope direct vision through the visual obturator may be employed, and the rectum inflated. The female proves more troublesome than the male as a subject for sigmoidoscopic examination, due to a greater depth of the sacrum in the former. Care must be taken to avoid mistaking for pathological conditions any of the three (the usual number) crescentic shelf-like folds which project into the rectum²⁰ (plicae transversales recti, or semilunar valves of Houston). Of these folds the largest is situated

upon the right side of the rectum and may serve as a rough landmark for the site of reflexion of peritoneum ($2\frac{1}{2}$ to $3\frac{1}{2}$ in. above anus). (See Fig. 19.) The upper and lower folds are on the left side and located from 1 to $1\frac{1}{2}$ in. above and below the middle fold, respectively. The upper fold marks the rectocolonic junction.

Other instruments used for examinations through the pelvic floor are the cystoscopic and vaginal speculum. There are obvious rewards for the surgeon who acquires skill in the use of the cystoscope and in the interpretation of cystoscopic findings. It is accepted as a rule that any female with abdominal symptoms should be examined vaginally. Bimanual palpation, both recto-abdominal and vagino-abdominal, may prove of special value to the abdominal surgeon, since the external hand frequently can direct a tumor mass against the internal hand, or otherwise so increase intra-abdominal pressure as to greatly facilitate the examination.

Not only may the surgeon introduce objects into the orifices of the pelvic floor, but so also may the patient. Rectal foreign bodies, once they have passed the internal sphincter, tend to travel upward through the descending colon and may even be carried as far as the cecum. The explanation of this fact is found in the reverse peristalsis or anastalsis observed in the large bowel. This intestinal current, which is normal in no other part of the gastrointestinal tract, serves the purpose of keeping the contents of the large bowel from too prompt evacuation and insures a more complete removal of liquid and nutrient elements, with the formation of the semisolid mass constituting the normal stool. Foreign bodies which have been carried upward may become so lodged or incarcerated that they cannot be removed by the aid of enemas, irrigations or purgatives, and hence necessitate abdominal operations for their recovery.

The pelvic floor is no less interesting to the abdominal surgeon as a portal of exit than as a portal of entry. Blood, mucus and parasites discharged with the feces are indicative

Bimanual or

Palpation

Rectal Foreign
Bodies

Alvine Dis-
orders and Abdominal
Disorders

FIG. 20. Value of discharges through the anus in abdominal diagnosis.

of some ulcerative or other pathological process in the intestinal tract. Equally important, the presence of an abnormal alvine (*L. alvus*, belly) discharge may prove an unmistakable guide to some disorder of an organ which is an outgrowth of the primitive enteral canal. Thus biliary disease is indicated by the passage of gallstones or clay-colored and frothy stools, while the presence of steatorrhea (excess of fat) and azotorrhea (excess of nitrogenous materials) suggest pancreatic disfunction (see Fig. 20). Likewise the lung and upper respiratory tract retain a communication with the intestinal canal and may contribute materials to its contents which can be recovered through the anus. Tubercle bacilli swallowed with mucus from the bronchial tube may pass through the enteral tract or may set up a secondary tuberculous enteritis. Germs from an acute infection of the lymphoid tissue of the tonsils may be discharged with the intestinal content or may even initiate such a pathological change as an involvement of Peyer's patches (see Henoch's purpura) or of the lymphoid tissue of the vermiform appendix. Such direct routes of extension are secondary in importance only to the hematogenous pathway.

With severe degrees of prolapse or procidentia of the rectum (*L. procidere*, to fall down or forward), the peritoneal pouches of the pelvis may be actually carried outside of the pelvic floor. Thus in resecting a protruding and redundant mass, the peritoneal cavity may inadvertently be entered, an accident which makes a complicating putrefactive infection and peritonitis exceedingly likely. Again, the herniated pouch may contain prolapsed small bowel. In such a case careless operative interference may be attended by even greater damage. A complete rectal herniation, also known as an archocoele (*G., archos*, fundament + *kele*, tumor,) must be treated by abdominal exposure or rectopexy (*G. pexis*, fixation) rather than by perineal excision. With all rectal prolapses beyond those of the second degree the possibility must be borne in mind that abdominal contents may constitute a part of the external mass (see Fig. 21).

Pelvic Herniation
of the Peritoneum

The Open and the Closed Cavity

In interpreting the influence of sex upon the incidence of abdominal diseases the anatomical fact should be kept in mind that in the female there is a direct communication be-

FIG. 21. Rectal prolapse with intestines herniated into pararectal pouch; associated with prolapsus uteri and rectocele from lacerated perineum. (From Keen's Surgery, W. B. Saunders Co.)

tween the peritoneal cavity and the outside of the abdomen by way of the uterus and Fallopian tubes. Normally a mucous plug at the uterine cervix, the tightly contracted cervical sphincters, and the overlapping fimbriae at the peripheral end of the tubes serve to effectively seal the female peritoneal cavity.

Further Considerations Regarding the Pelvic Floor

Additional important considerations concerning the pelvic floor appear in other chapters. During the study of the abdominal circulation the clinical significance of chronic passive congestion (see Fig. 22) thrombosis and embolism within the rectal and pelvic regions is discussed; in the section dealing with the enteral tract the value of the rectal route for the administration of medications and fluids is considered; in the review of visceral neurology the relationship between pruritus ani and intra-abdominal pathological conditions receives

attention, and the significance for the differentiation between pelvic and abdominal disorders of rigidity of the levatores ani is investigated (muscles innervated on their pelvic surface

FIG. 22. Hemorrhoids and caput medusae as caused by obstruction to the portal circulation.

by the anterior rami of the third and fourth sacral nerves and on their perineal surface by the perineal branch of the pudendal nerves); in the study of peritoneal drainage, anterior colpotomy is described (see Fig. 23). In like manner, other details concerning the pelvic floor are reserved for pages which follow.

C. THE ABDOMINAL WALLS

The Thoracic Box
vs. the Abdominal
Bag

There exists a striking contrast as to composition between the walls of the upper and the lower divisions of the trunk.

FIG. 23. Anterior colpotomy for drainage of pus which has gravitated to lowest portion of peritoneal cavity. Penetrating abscess wall. The sharp-pointed scissors, under the guidance of the finger, have been introduced into the mass and then opened widely. (From Crossen's Operative Gynecology, C. V. Mosby Co.)

Thoracic walls are composed largely of bone, while abdominal walls are made up chiefly of muscles. The walls of the thorax are rigid; those of the abdomen are soft. This distinction is

implied in the names which have been given to these respective divisions of the body. The word chest means a box (A. S. *cest*, box) and the term thorax, a plate of armor (Gr. *thorax*, a cuirasse). The word belly, on the other hand, signifies a bag (L. *bulga*, bag) or something capable of being alternately filled and emptied. The abdomen is synonymously known as the venter (L. *venter*, belly), just as a chamber of the heart, alternating with the rhythmic cardiac cycle between a contracted and a relaxed state, is termed a ventricle; and as the stomach, periodically changed in size with the intake and output of food, is known as a ventriculus (i.e., a little, or small model belly). Functional activities within the abdominal cavity, as within the thoracic cavity, depend quite largely upon peculiarities in the composition and structure of its walls.

1. *The Muscular Walls.* When speaking of "abdominal muscles" the surgeon often refers simply to the large, flat muscles of the anterior abdominal wall. This is true because patients are usually examined as they lie in the dorsal decubitus, making the anterior wall the presenting surface. This group, however (recti, transversi, external and internal obliques) far from constitutes a complete list of abdominal muscles and it fails to suggest the conception that the abdomen is a muscular bag. The muscles of the posterior wall together with those of the floor and roof, functionally speaking, are coordinated in their action with those of the anterior wall, making possible wide changes in the capacities and pressures within the venter, or belly. The quadratus lumborum, psoas major and minor, iliacus, levator ani, and coccygeus muscles are as deserving of consideration as are the diaphragm and the transverse, straight, and oblique muscles of the front and sides of the abdomen (see Fig. 25). But in addition, the surgeon must know many anatomical details concerning any and all of the muscles which he may sever when entering the abdominal cavity. Thus numerous muscles which support or move the extremities overlie portions of the abdomen, for example the latissimus dorsi and the glutei, and these must be dealt

Muscles Encountered in Entering the Peritoneal Cavity

FIG. 25. Muscles of posterior and lateral abdominal walls. (Spalteholz.)

with when operations are performed in special regions, as must also the intercostals and certain other muscles of the thorax when the peritoneal cavity is approached from above.

**Muscles Involved
by Reflex Spas-
ticity**

When the abdominal walls are studied for a review of operative surgery, anatomical considerations are of chief importance, but when the abdominal muscles are reviewed for the purpose of gaining some clinical understanding of the reflex spasticities which may accompany disorders within abdominal organs, the major emphasis must be placed upon the innervation, central connections and function of the muscles rather than upon their positions. The reflex mechanisms by which tension variations of the contractile tissues are produced, prove complicated. Abdominal organs are connected with the spinal cord through the white rami communicantes of the sympathetic nerves^{21,22} (the thoracolumbar division of the involuntary nervous system; see Visceral Neurology) and these white rami pass to the spinal cord, exclusively between the fifth thoracic and the second (or third) lumbar cord levels (Th₅-L₂)²³ (see Fig. 24). Skeletal muscles which exhibit clinical evidence of reflex spasticity from diseases within intra-abdominal viscera are those having motor neurones which are situated in the anterior horns of these particular cord levels (Th₅-L₂).

**Connecting Path-
ways Between
Abdominal Viscera
and Skeletal
Muscles**

That the study of gross anatomy alone is inadequate, in this connection, is shown by the fact that some of the muscles possessing such reflex associations with intra-abdominal structures are situated at a considerable distance from the abdominal cavity itself (examples: rigidity of the muscles innervated through the third and fourth cervical segments, due to irritation of the central portion of the diaphragm, the afferent stimuli traveling by way of the phrenic nerves; spasm of the cremaster muscle with ureteral colic, the reflex being produced through afferent stimuli passing over the white rami communicantes to reach motor neurones of the first lumbar level of the spinal cord). On the other hand, some of the muscles which overlie the abdomen, and thus anatomically form part of its covering walls, possess no such reflex associations with abdomi-

nal viscera. For example, the latissimus dorsi overlies the abdominal cavity posteriorly, arising from as far downward as the crest of the ilium. But this muscle, being innervated exclusively by cervical nerves (C6-C8), has no direct nerve pathways which connect it with the organs of the abdomen. Similarly, the glutei muscles, maximus, medius and minimus, lie in part above the level of the pelvic inlet (hence overlie the lower part of the abdominal cavity), but since these muscles are innervated solely through levels between the fourth lumbar and the second sacral segments of the cord (L4-S2), they could have no direct reflex connection with abdominal organs by way of the white rami communicantes. All muscles with the function of moving any part of the upper extremity derive their motor neurones from the fifth cervical to the second thoracic cord levels (C5-Th2) and the muscles related in an analogous fashion to the thigh, leg, and foot are innervated from the second lumbar to the third sacral cord level (L2-S3). Almost all of these muscles, then, possess no direct reflex pathways associating them with abdominal organs and for the present study of the muscular walls of the abdomen the cavity will be considered simply as a part of the ovoid mass which constitutes the trunk (see Fig. 1), a mass "devoid of extremities, or parts designed to support or move these extremities." (For details concerning the relationship between the muscles of the extremities and intra-abdominal disorders see section dealing with Visceral Neurology.)

The Muscles of
the Extremities

Studied with reference to morphology and to central connections, then, the list of skeletal muscles of the body wall which may show reflex spasticities from intra-abdominal disorders is as follows²⁴ (see Fig. 26):

Anteriorly

1. M. rectus abdominis
2. M. diaphragma (sternocostal portions)
3. * M. pyramidalis abdominis

Laterally

A. Abdominal Group

1. M. obliquus externus abdominis

2. M. obliquus internus abdominis
3. M. cremaster
4. M. transversus abdominis

FIG. 26. Innervation of skeletal muscles which show reflex spasticities from intra-abdominal disorders.

B. Thoracic Group

1. MM. intercostales externi
2. MM. intercostales interni
3. M. transversus thoracis
4. * MM. levatores costarum
5. * MM. subcostales

Posteriorly

1. M. quadratus lumborum
2. M. diaphragma (crura)
3. * M. serratus posterior inferior
4. M. iliopsoas (psoas major, psoas minor, (iliacus)
5. * M. sacrospinalis (O. T. erector spinae), and other smaller "muscles of back."

* Signifies muscles of relatively less clinical importance.

The cremasters are included because they arise from the lower portions of the internal oblique muscles. The psoas major and minor are included because they are the only muscles passing to the thigh which attach the lower extremity to the trunk and pelvic girdle; i.e. they move not only the lower extremity but the trunk as well. The peripheral portions of the diaphragm are included because they are innervated through the lower thoracic nerves in contrast to the central portion which is innervated through the phrenic nerves (C₃, C₄, C₅).

Little comment need be given to reflex rigidities of the recti, transversi and external and internal obliques, for these are generally and well appreciated. But certain equally constant analogous rigidities are not so commonly recognized. It would seem unreasonable to believe that any of these muscles, possessing as they do motor nerves and central connections, should fail under certain conditions to be thrown into reflex spasticity, even though this spasticity be imperfectly understood, difficult to detect, or appear to be of relatively less clinical value. Spasticities of the intercostal muscles and diaphragm from abdominal disorders are, perhaps, not generally appreciated, but account for the dyspnea which often accompanies such upper abdominal conditions as acute cholelithiasis and cholecystitis. Reflex spasms of the quadratus lumborum, psoas, and cremaster muscles are as important in many renal and ureteral disorders as are rigidities of the anterior muscles from acute diseases of the appendix or gall bladder. No clinical tests have been described in regard to spasticities of the pyramidalis, serratus posterior inferior, the transversus thoracis; and probably, from the small size and the anatomical positions of these latter muscles, they are of relatively less clinical value, yet their central connections demand that they be included in the present list.

Abdominal Rigidities; Reflex; Spasticities

The accompanying chart tabulates, for convenience, many of the following points with which the abdominal surgeon should be familiar concerning each muscle: its origin, insertion, function, meaning of name, innervation by peripheral nerves,

relationship to spinal segmentation and to the involuntary nervous system; also the position or body posture caused by its continued contraction, and points of special clinical significance.

After a brief discussion as to methods for detecting reflex muscular rigidities, clinical points will be reviewed concerning the muscles which have been tabulated with reference to the diagnosis of intra-abdominal diseases.

The Examination
for Rigidity

While spasm of a muscle may produce a characteristic alteration in position or a typical posture which is readily detected by inspection alone, chief reliance for the discovery of muscular rigidity must be placed upon palpation. Abdominal palpation is performed with the flexor surfaces of the fingers and hand, laid almost flat upon the belly walls. A slow, steady pressure, combined with slight flexion of the fingers, gives the examiner a means for estimating the resistance present. To poke at the abdomen with the fingertips alone produces a voluntary muscle spasm. Spasm is also induced by examining hands which are cold. The hands may be warmed by dipping them in tepid water, by holding them for a few moments within the axillae, by rubbing them briskly together; or the examination may be commenced with a layer of cloth (gown, sheet, towel) between the examiners hands and the skin of the patient. The patient lies in a relaxed position, arms at the side, head flat, thighs and legs resting upon the bed, or the thighs are slightly flexed over a bolster or pillow (attempts to have the patient keep his own thighs flexed without support may result in more rather than less abdominal tension); the patient is instructed to breathe deeply and quietly through the mouth; talking, on the part of the patient, is discouraged, but the examiner both by his tone and manner attempts to quiet the patient and to divert attention from the examination. The mind of the examiner, on the other hand, keeps pace with the examining hand and an attempt is made to visualize intra-abdominal structures. If the patient has complained of symptoms in a certain region of the abdomen, palpation

commences at a distance from this point and the area supposedly involved is secondarily approached.

To detect slight degrees of involuntary spasm requires

Comparative
Bimanual Abdomi-
nal Palpation

FIG. 27. Method of bimanual comparative abdominal palpation. Note how fingers of left hand sink deeply into abdominal wall while those of right hand undergo a lessened descent, due to rigidity of right lower quadrant (appendicitis). Exactly equal pressure must be exerted by the two hands.

great care and as a rule clinical experience. A valuable method suggested by Murphy is known as "bimanual comparative abdominal palpation."²⁵ Here, in place of examining first one region, then another, by means of a single hand, the examiner places his two hands in analogous positions upon the belly wall (example, the two lower quadrants) and by increasing pressures slowly and equally with the two hands, observes whether one hand sinks more deeply into the abdominal wall than the other (see Fig. 27). "Compare the manner in which the examiner's left hand sinks into the patient's left iliac fossa to the lessened descent of the right hand on the side

of the slightly inflamed appendix." Differences in abdominal tension which might otherwise easily be overlooked may be detected and objectively demonstrated by the use, after practice, of this method of comparative palpation.

**Palpation through
the Indrawn Wall**

Abdominal palpation proves particularly unsatisfactory when the patient is muscular or is apprehensive regarding the examination. Voluntary rigidity prevents the examining fingers from reaching a sufficient depth satisfactorily to search for tumors and misplaced or enlarged organs. The following technical "dodge" may be employed to put the overactive abdominal muscles to direct use and to remove apprehension, changing the patient's mental attitude from one of guarded resistance to one of cooperation. Carry the examining fingers to whatever depth they will readily sink with slow steady pressure; then ask the patient to "draw the abdominal muscles inward," that is, to make his abdomen "as thin as possible;" now ask the patient to relax completely and to breathe with the mouth wide open. It will be found that as the abdominal muscles are drawn inward the examining fingers sink to a surprisingly greater depth and as the patient relaxes, the abdomen may be palpated at the new level with relative ease and satisfaction (see Fig. 28). This method of examination might be designated "palpation through the indrawn wall."²⁴

**Palpating with a
Depressed Costal
Arch**

Another aid to palpation consists of making inward pressure upon the lower ribs anteriorly, thereby shortening the distance between the points of origin and insertion of the anterior abdominal muscles of that side, adding to their relaxation. The technic for the procedure is as follows:²⁴ Place the "heel" of the dorsiflexed hand (i.e. the thenar and hypothenar eminences) over the hypochondrium upon the side to be palpated (i.e. over the lower portion of the anterolateral surface of the thoracic cage); make steady pressure upon the ribs until they sink definitely backward; with the opposite hand palpate the subcostal area and upper quadrant of this side of the abdominal wall. It will be found that as the cage

FIG. 28. Abdominal palpation with indrawn wall.

- a. Voluntary rigidity prevents the examining fingers from sinking into the abdominal wall.
- b. Examining fingers sink deeply into abdominal wall as the patient draws his anterior wall sharply inward.
- c. As the patient then relaxes the examining fingers remain deep within the wall, facilitating the examination.

is pressed inward, the fingers of the examining hand sink to a lower level, enhancing the ease of abdominal examination. This method might be designated "palpating the abdomen

FIG. 29. Abdominal palpation with depressed costal arch.

- A. Voluntary rigidity renders the examination unsatisfactory.
- B. As the costal arch is pressed inward the muscles of the anterior abdominal wall are relaxed, facilitating the examination.

with a depressed costal arch" (see Fig. 29). Abdominal palpation conducted with the aid of both the indrawn wall

and the depressed costal arch increases to a maximum the total area of abdomen which comes within reach of the examining fingers.

Respiratory difficulties may readily be demonstrated clinically as an accompaniment of acute abdominal disorders as well as of thoracic diseases. In numerous isolated accounts a reflex spasticity of the muscles of inspiration observed with pathological changes within the abdomen has been convincingly described. Postoperative respiratory changes were discussed over a quarter century ago (Czerny²⁶) and suggested as one possible cause for the development of postoperative pneumonia. Diaphragmatic spasticity has been reported as occurring with perforated and perforating gastric ulcers (Hubeny,²⁷ 1916; Hughes²⁸ 1917). Reflex spasticity of the diaphragm, confirmed by auscultation and roentgen-ray examinations, was demonstrated by Sale²⁹ (1918) in 19 cases of acute appendicitis (Sale's phenomenon). Dyspnea from acute pancreatitis has been frequently observed (Pottenger,³⁰ Cope³¹). Dyspnea has been stated to be present in 71 per cent of cases of acute cholelithiasis (Bodenstab,³² 1918, in a study of the symptoms in 500 cases of gall-bladder disease). That these convincing observations have not gained general recognition, however, is apparent in the fact that textbooks dealing with acute abdominal disorders rarely make mention of such reflex dyspnea as a symptom. Even those current reference books written for the express purpose of listing the various possible causes of individual signs and symptoms, discuss over a hundred conditions giving rise to the several types of dyspnea without giving any indication that this symptom (dyspnea) might arise as a reflex from acute diseases of abdominal organs such as the stomach, gall bladder, pancreas, or appendix. All too frequently no history is sought of "inability to take a full breath" or "catches in breathing" when interviewing patients with suspected cholelithiasis or cholecystitis.

Reflex spasticity of the respiratory muscles arising from abdominal disorders, is produced through the lower intercostals

Reflex Dyspnea
from Abdominal
Disorders

Dyspnea with
Cholelithiasis

Inspiratory
Dyspnea

(muscles innervated from the 5th to the 12th thoracic levels of the cord), through the peripheral portions of the diaphragm (innervated by the lower intercostal nerves), and through the serratus posterior inferior, (10th and 11th thoracic levels, posterior rami) and other lesser muscles of respiration, levatores costarum, subcostales and the transversus thoracis which receive innervation through the anterior rami of the lower intercostal nerves. The dyspnea takes the form of difficulty with the inspiratory phase of the respiratory cycle, particularly upon attempts at forced inspiration.

Methods for
Detecting Spas-
ticity of the
Diaphragm

Since the diaphragm cannot be directly palpated, diminished action of this muscle upon a single side may be detected by the following methods. (a) By auscultation. Here there is found a quantitative difference between the involved and non-involved sides as to the loudness, length, and intensity of the inspiratory murmur (feebleness upon the right side with cholecystitis). (b) By roentgen-ray examination. Sales states that "the Roentgen ray in every case substantiated the stethoscopic findings;" with acute appendicitis the right dome was found to be flatter than the left and showed a diminished excursion (normally if any difference between the two domes can be detected it is the right side which is more dome-shaped and has the wider excursion). (c) By direct observation of the diaphragmatic phenomenon, using the same methods as utilized when searching for Litten's sign (see section on eponyms); (the diaphragmatic phenomenon is retarded and the excursion lessened upon the involved side). (d) By percussion, i.e. percussing the lower thorax posteriorly first during quiet breathing, then during forced inspiration, and measuring the difference in level of the dullness present, thus obtaining the estimate of the excursion of the diaphragm upon that side (comparison of the two sides shows a diminished excursion upon the side involved).

Differentiation
between Thoracic
and Abdominal
Disorders

This involvement of certain of the muscles of respiration by both abdominal and thoracic disorders adds to the difficulties of differential diagnosis. It should be recalled, however,

that when the afferent or sensory stimuli arise from above the diaphragm (thoracic diseases) additional muscles of respiration are usually involved (levels above the 5th thoracic) and reflex spasticities in the upper thorax and in the muscles attached to the shoulder girdle are added to the clinical picture (see trapezius test in differentiating between basilar pleurisy and acute appendicitis etc.; (Visceral Neurology). Here the dyspnea tends to be relatively more acute and to affect both phases of the respiratory cycle, while abdominal rigidity, if also present, tends to be greatest immediately below the costal arches. When the afferent or sensory stimuli arise from below the diaphragm, upon the other hand (abdominal disorders), the dyspnea is relatively less in degree, is inspiratory in character, and is not associated with spasticities or tenderness in the muscles of the upper portions of the thorax or those directly concerned with movements of the upper extremity. With abdominal diseases yielding the dyspnea, there is also present a marked rigidity of the abdominal muscles and this is greatest, not immediately below the costal arches, but over the region well known to be reflexly associated with the abdominal organ involved. In the presence of dyspnea of the spastic type, then, an estimate should always be attempted as to which is the greater: the thoracic rigidity (as evidenced by diminished expansion) or the abdominal rigidity (as detected by palpation), and the full extent of the involvement of thoracic muscles should be determined. The data gathered from physical examination, as in any differential diagnosis, must be most carefully correlated with a complete and detailed history. Clinical errors in which a needed abdominal operation is delayed under the impression that the disease present is thoracic are relatively uncommon. Blunders in which a needless abdominal operation is performed when the disease is actually present within the chest (pleurisy, pneumonia, mediastinal hemorrhage mistaken for acute appendicitis) occur with relative frequency. It must be recalled (see Section I, the abdominal roof) that all of the nerves passing to upper abdominal viscera must traverse the

Correlation of
Physical Findings
with History

thoracic cage before reaching their destination, hence they are exposed to direct irritation from thoracic disorders.

Spasticity of the cremaster muscles gives rise to accentua-

Cremaster Spasm and the Subinguinal Syndrome

FIG. 30. Subinguinal syndrome of renal colic. Triangular cutaneous area of clinical value in determining presence of intra-ureteral tension.

tion of the cremasteric reflexes, to corrugation of the scrotal skin, and to retraction of the testicle. It would be difficult to overestimate the value of cremaster spasm in the differentiation of renal colic from acute intra-abdominal conditions such as acute appendicitis and acute cholelithiasis. Given a patient with severe colic, the detection by simple inspection of cremaster spasm clearly indicates the correct diagnosis, for this sign constitutes presumptive evidence of renal or ureteral colic. Cremaster spasm is usually associated with the other phenomena of the so-called "subinguinal syndrome" of acute ureteral colic^{33,34} (i.e. hyperesthesia limited to the ureteral skin triangle of the thigh, altered responses to heat and cold within this area, local vasomotor phenomena, tenderness of the isolateral testicle) (see Fig. 30). (See Visceral Neurology.)

Spasticity of the quadratus lumborum causes the trunk to be flexed laterally toward the involved side (inability to assume an erect posture). Rigidity of this muscle, as that of other muscles of the loin, is caused by renal or ureteral disorders and by diseases of other structures innervated through upper lumbar cord levels, rather than through diseases of upper abdominal organs which have their central connections at thoracic cord levels.

Lateral Flexion of
the Trunk with
Renal Colic

Spasticity of the iliopsoas similarly (lumbar innervation) is reflexly produced through lower abdominal, renal or pelvic disorders rather than by upper abdominal conditions. The psoas muscle, however, due to its position immediately beneath the parietal peritoneum, may be directly involved or irritated by inflammations or productive infiltration over the muscle. Continued contraction of the iliopsoas causes a flexion posture of the thigh. Reflex spasticity of lesser degrees may be detected by the so-called psoas test (Treves;³⁵ Cope³⁶) which consists of searching for muscular resistance and pain as the lower extremity is passively hyperextended. In making this examination the patient may lie face downward and the thigh be then lifted upward, or the patient may lie on the side opposite to the one being tested, as the lower extremity is slowly forced backward.

Psoas Test;
Spastic Flexion of
the Thigh

To illustrate the manner in which the psoas may be thrown into a state of spasticity by organs which are not directly connected with the muscle by way of the spinal cord and the white rami communicantes but which involve the muscle directly: The patient with an acute appendicitis may have a rigidity of the right lower quadrant and also a flexion posture of the thigh or positive psoas test, both being due to muscle spasm, but the rigidity of the anterior and lateral abdominal muscles represents an early involvement and is a reflex spasticity produced through the involuntary nervous system, while the rigidity of the posterior muscles represents a later and a direct involvement caused by a local irritative process from the overlying inflammation and is produced by way of the cerebrospinal system.

Viscerogenic
Reflex Spastici-
ties vs. Peripheral
Nerve Irritations

All of the spasticities referred to will again be considered in the section dealing with Visceral Neurology and at that point attention will be focused upon the specific neurone pathways and synapses which make possible alterations in the skeletal muscles which may be detected during the clinical examination.

Hoarseness with
Colics

There are many motor phenomena associated with abdominal disorders other than those which involve the muscles of the abdominal walls *per se*. There may occur (by way of the vagus) a spastic contraction of the laryngeal muscles, giving rise to hoarseness as observed with severe colics (and although Hippocrates spoke of "the muffled voice of colics,"³⁷ how often still is the patient unjustly maligned for speaking in a whisper); there may occur involvement of the muscles associated with the eye (by way of the cranial autonomies) with a resulting disturbance of vision; the tensor tympani muscle of the inner ear may be reflexly involved (vagus) with a resulting tinnitus aurium; through the nervus erigens there may occur analogous spasticities of smooth muscles in the rectal and perirectal regions. At times the motor responses from intra-abdominal disorders represent viscerovisceral phenomena, where both the afferent and efferent stimuli travel exclusively within the involuntary or vegetative nervous system (example: reflex pylorospasm); at other instances they are of the visceromotor type, where the afferent stimulus travels by way of the involuntary system but the efferent stimulus travels by way of the anterior root fibers of the cerebrospinal system (example, a peripheral abdominal rigidity from an acute inflammation or colic); and in still other cases the muscle spasm is simply the result of a peripheral nerve irritation, having no afferent but merely an efferent pathway (example, spastic adduction of the thigh from pressure upon the obturator nerve as it passes into the pelvis, John Hilton.³⁸) In subsequent pages which deal with symptomatology, such motor responses are taken up one by one, in detail, an attempt being made both by charts and words to give as accurate as possible an explanation of the most common of the clinical signs.

Viscerovisceral
vs. Visceromotor
Phenomena

It is obvious that the surgeon must thoroughly study *all* of the muscles which form a part of the abdominal walls and that even this is not sufficient since there are instances in which intra-abdominal diseases may cause motor phenomena at every level of the cerebrospinal system, some in the cranial, others in the cervical, and still others in the thoracic, lumbar, or sacral levels (Visceral Neurology).

2. *The Bony Walls.* No portion of the body receives less skeletal support than the abdomen. The only bones which belong exclusively to the abdominal division of the trunk are the five lumbar vertebrae. The abdomen, as already observed, is a muscular bag. Yet while the abdominal cavity receives but little skeletal support it by no means follows that it receives inadequate skeletal protection. Protection is obtained both from the bones of the thoracic cage and from those of the pelvic walls. The abdomen, due to the domed shape of the diaphragm, has been seen to extend well within the thoracic cage which serves to protect all the organs of the supracolic division of the peritoneal cavity. Similarly, the abdomen in its lower aspects (within the protection of the iliac bones) blends with the true pelvis and the separation of abdomen and pelvis is purely arbitrary. A list of the bones which overlie, and therefore in reality form walls for the abdominal cavity are:³⁹ a variable portion of fifteen of the twenty-four ribs; the five lumbar vertebrae, with their numerous processes and intervertebral discs; the xiphoid process of the sternum (cartilaginous); the iliac bones; the upper border of the sacrum; and portions of the pubes.

Posteriorly and laterally, then, the abdomen is provided with almost complete bony protection. And upon the sides, the lower ribs and their cartilages extend to within one to three finger-breadths of the iliac crests! Upon the lateral wall of the abdominal cavity the purely muscular portion is simply this narrow interosseous space of but 1 to 3 inches in width. At the level of the tip of the eighth costal cartilage (intercostal angle), not over 10 per cent of the circumference

domen provide a convenient system of landmarks. Such points are of use in outlining the various viscera, in localizing tumors, in determining the exact sites for the injection of local anesthetics. The landmarks of the spinal column and os coxae are fixed and constant. Those connected with the costal margins are inconstant in position since the thoracic cage is attached only posteriorly and is movable. In the portion of this chapter headed Abdominal Topography, details concerning the clinical use of these bony points are discussed.

It has been said that every abdominal examination should begin with an inspection of the intercostal angle.⁴⁰ Differences of the most profound nature exist between patients having narrow and those having wide intercostal angles.⁴¹ These differences concern the intra-abdominal arrangement of the organs, intra-abdominal pressure and pressure variations; also matters pertaining to surgical diagnosis and treatment (see Fig. 31). Under the headings Visceroptosis, and Mesenteric Ileus will be found full discussions regarding the causes and results of variations in the angle formed by the costal margins. A study is made of the relationship between non-rotation of the bowel or partial rotations of the bowel and the secondary bony changes within the thoracic cage; the visceroptotic individual is considered as the victim of a congenital constitutional defect and as one who possesses a fundamental weakness of connective tissue. So important an index as to the type of the individual is the configuration of the intercostal angle that the observation of this bony landmark should, perhaps, be the first step in any abdominal examination.*

[* The study of the abdominal walls will continue in the March issue of the Journal.]

EPONYM

JAMES MARION SIMS

- Eponym:** Sims' position.
The left lateral decubitus.
- Name, Nativity:** James Marion Sims. Lancaster District, South Carolina, U. S. A.
- Birth, Death:** Born, January 25, 1813. Died November 13, 1883.
- Connections:** A founder of the State Hospital for Women in 1855 (New York City).
Made Governor and Senior Consulting Surgeon of Woman's Hospital (New York) in 1868.
Surgeon-in-Chief of Anglo-American Ambulance Corps in 1870 (Franco-Prussian War).
Member of Board of Surgeons, Woman's Hospital, 1872.
President of American Medical Association in 1876.
President of American Gynaecological Society in 1880.
Received degree of Bachelor of Arts at the College of South Carolina in 1832.
Began the study of medicine in the office of Dr. B. C. Jones, a practitioner of Lancaster, S. C.
Took his first series of lectures in medicine at the Medical College of Charleston, South Carolina (1834).
- Education:** A graduate from Jefferson Medical College, Philadelphia, in 1835.
- Source of Eponym:** From book of author: *Clinical Notes on Uterine Surgery*, published in London in 1866 by Robert Hardwicke (pp. 23-24).
- Other Writings:** His first contribution to surgical literature was his paper on *Trismus Nascentum* appearing in the *American Journal of Medical Sciences* in 1846.
Silver Sutures in Surgery (1849).
Vesicovaginal fistula (1852).
The Careful Aseptic Invasion of the Peritoneal Cavity for the Arrest of Hemorrhage, the Suture of Intestinal Wounds, and the Cleansing of the Peritoneal Cavity, and for all Intraperitoneal Conditions (1881).
(See indices for other Papers.)
- Discussion of Eponym:** Sims, while practicing in Alabama, was called to attend a country woman who had sustained an acute displacement of the uterus due to a fall from a horse. While examining his patient digitally by the vaginal route with the patient upon her knees, he was suddenly unable to feel the displaced uterus and the patient was at that moment relieved of her symptoms. Sims was unable to account for this until, as his patient assumed the dorsal decubitus, there was a sudden expulsion of air which gave a ready explanation of the replacement of the uterus. Thereafter Sims employed the knee-chest position as a routine for vaginal examinations and described in his writings how air, with its 14 pounds pressure to the square inch, aided in dilating the vaginal walls; he then devised his special speculum (first a bent spoon) to aid in the admitting of air for the visual examination. Later, after coming to New York, he changed to the routine use of the left lateral posture for pelvic examinations, using the knee-chest posture only for special examinations or treatments.
- Points of Interest:** Sims, "a kind-hearted but impulsive man, was one of the most original and gifted of American surgeons."
His career as a specialist in New York City was preceded by eighteen years of general practice in Alabama.
Sims moved to New York as the result of two years of sickness in which he wandered about but was unable to practice (persistent diarrhea which had proved generally fatal to patients remaining in Southern states).
With a growing family and in straightened circumstances he settled in the outskirts of New York City (1853) at what is now Madison Avenue at 29th Street. There was at that time no first-class dwelling nearer than 23d Street, and the location afforded a full view of the East River. Sims' first patient, who suffered from vesicovaginal fistula, was referred by Dr. Valentine Mott.

PREFACE.

On

WITH SPECIAL REFERENCE TO THE

MANAGEMENT OF THE STERILE CONDITION.

By J. MARION SIMS, A.B., M.D.

LATE SURGEON TO THE WOMAN'S HOSPITAL, NEW YORK.

Fellow of the New York Academy of Medicine; of the New York Pathological Society; of the New York Historical Society; of the New York State Medical Society; of the Royal Medical

possible, and for this reason the patient is rolled over on the front, making it a left lateral semiprone position. The nurse or assistant standing at her back pulls up the right side of the nates with the left hand, when the surgeon introduces the speculum, elevates the perineum, and gives the instrument into the right hand of the assistant, who holds it firmly in the desired position. .

FIG. 32. Title page and preface page from Sims' book in which he describes the "Sims' position."

Continued from p. 82

During the Civil War, for political reasons Sims moved to Europe where he resided in London and Paris for six years.

Due to the fact that outsiders were stopped from visiting his clinics and that his plea to admit cancer patients to the hospital was denied, Sims resigned from the Woman's Hospital in 1874. He had no further connections with this institution until shortly before his death when he again became a member of the consulting board.

In 1894 European and American admirers erected a statue to the memory of James Marion Sims, in Bryant Park, New York City.

EPONYM

GEORGE RYERSON FOWLER

Eponym: Fowler's position.

The semi-sitting posture for the treatment of acute peritonitis.

Name: Nativity: George Ryerson Fowler, New York City.

Birth, Death: Born, December 25, 1848. Died, February 6, 1906.

Connections: His first appointment came in 1883 as Surgeon to St. Mary's Hospital at Jamaica, L. I. Four years later he was one of the two attending surgeons at the Seney Methodist Episcopal Hospital in Brooklyn.

Later, Surgeon-in-Chief to the Brooklyn Hospital.

Other hospital appointments: Consulting surgeon to the Relief Hospital of the Eastern District; to Norwegian Hospital.

For five and one-half years Professor of Surgery in the New York Polyclinic Medical School; later Professor Emeritus of that institution.

Examiner in surgery to the Board of Regents of the University of the State of New York.

Chief Surgeon of Division, United States Volunteers, being commissioned by Pres. McKinley with rank of Major.

First President of the Brooklyn Red Cross Society (1890).

Delegate to the International Medical Congress in Moscow (1897) and Paris (1900).

Education: Graduated (M.D. degree) from Bellevue Hospital Medical College in 1871.

Took no internship but went directly into general practice.

Source of Eponym: Fowler contributed his article titled, "Diffuse Septic Peritonitis, with Special Reference to a New Method of Treatment, namely the Elevated Head and Trunk Posture to Facilitate Drainage into the Pelvis; with a Report of Nine Consecutive Cases of Recovery" to the *Medical Record* of New York for April 14, 1900.

Other Writings: Wrote a treatise on appendicitis in 1894. This was revised and enlarged in 1900.

Associate Editor of the *Annals of the Anatomical and Surgical Society*, later the *Annals of Surgery*.

At the time of his death Fowler has completed two volumes on General Surgery.

Did important work in thoracic surgery, his name being particularly associated with the subject of decortication of the lung in the treatment of chronic empyema.

Discussion of Eponym: It is of interest to note that the position for which Fowler is known was first suggested by his son and assistant, Dr. Russell Fowler, as a possible aid in preventing postoperative vomiting. The senior Fowler, noting the favorable effect of the position upon a patient with acute peritonitis, made an extensive study of the reasons for the observed improvement. Dr. George Fowler, in his writings, gives full credit to his son for suggesting the elevation of the head.

The Fowler's position is at present not infrequently spoken of as the full sitting posture, while the position in which the patient's head is elevated by 12 to 18 inches is termed the modified Fowler position. From the photostat here reprinted it is seen that the original "Fowler position" is semi-sitting posture. The semi-sitting posture for use in surgery had been vigorously advocated over a hundred years before by White¹ whose original article shows special tables for maintaining the patients in the desired position; but it was undoubtedly the work of Fowler which popularized the postural treatment for peritonitis.

Points of Interest: In regard to his text on surgery it has been said: "The book is the epitome of his life; into every page of it he infused his own personality. In its clearness of diction, comprehensiveness of treatment and the practical directions for resort to surgical relief, it is unsurpassed by any book of its day."

Fowler, with the aid of his son, corrected the proof for this text but never lived to see his own book.

Fowler seemed of tireless disposition and often after full days of operating wrote, in his own library, far into the night.

DIFFUSE SEPTIC PERITONITIS, WITH SPECIAL REFERENCE TO A NEW METHOD OF TREATMENT, NAMELY, THE ELEVATED HEAD AND TRUNK POSTURE, TO FACILITATE DRAINAGE INTO THE PELVIS. WITH A REPORT OF NINE CONSECUTIVE CASES OF RECOVERY.¹

By GEORGE R. FOWLER, M.D.,

NEW YORK,

PROFESSOR OF SURGERY IN THE NEW YORK POLYCLINIC; SURGEON TO THE METHODIST EPISCOPAL HOSPITAL, ETC.

THE peritoneum is virtually an enormous lymph sac, and therefore peritonitis is lymphangitis. The absorbents of the structure of the peritoneum are represented by the lymphatics, and the protection which these afford against infecting agents by exudative material thrown out (thrombo-lymphangitis) to act as a defensive barrier by blocking the lymph channels serves to preserve the life of the subject, on the one

It was during the after-treatment of a case of diffuse septic peritonitis the result of early perforation of a violently inflamed appendix directly into the peritoneal cavity and between the coils of small intestine, and in which I had placed a glass drain as well as a number of wick drains deep in the pelvis, that the line of thought above expressed occupied my mind. My assistant, Dr. R. S. Fowler, had been in the habit of treating cases of vomiting following etherization by raising the head of the bed as high as possible consistent with comfort, thus bringing the force of gravity to bear in facilitating normal peristalsis. In view of the favorable course which the case then in hand was pursuing, it was determined to adopt this as a routine procedure for the purpose of facilitating the passage of septic fluids from the general peritoneal cavity to that of the pelvis, where, according to the reasoning above outlined, it would do but little harm, comparatively speaking, and from which locality it could be more readily removed by drainage methods. This has been done, and a further experience with the method seems to bear out the favorable opinion first entertained of this measure as of value in aiding to combat the mortality in this much-dreaded condition.

The angle assumed has varied somewhat, but I insist that the elevation of the bed from the horizontal shall be at least from twelve to fifteen inches. In order to prevent the patient from sliding down in the bed a large pillow is placed folded beneath the flexed knees, and upon this the buttocks rest. The pillow is prevented from sliding by a piece of stout bandage

passed through at the folded portion and secured to the sides of the bedstead.

The following is a list of the cases consecutively treated by this method to date:

CASE I.—October 17, 1899; Brooklyn Hospital. Diffuse septic peritonitis from a combined appendicular and adnexal lesion, originating, in all probability,

FIG. 33. Page from the *Medical Record* for April 14, 1900, containing Fowler's article in which he describes the "Fowler position."

Continued from p. 84

On February 2, 1906, while on a train bound for Albany, N. Y. to conduct examinations in surgery, Fowler was suddenly seized with acute abdominal pain. He was taken to a hospital in Albany where he directed that the surgeons do as they saw fit concerning his illness. He was operated upon for acute appendicitis but died on the fourth day from paralytic ileus.

EPONYM

JOHN BENJAMIN MURPHY

- Eponym:** Murphy's method of bimanual comparative abdominal palpation.
- Name:** John Benjamin Murphy. Appleton, Wisconsin, U. S. A.
- Nativity:** Born, December 21, 1857. Died, August 11, 1916.
- Birth, Death:**
- Connections:** First appointments were to the surgical staff of the Cook County Hospital and the Alexian Brothers Hospital of Chicago.
 Professor of Surgery, Northwestern University (1905-1916).
 Taught surgery also in the University of Illinois, and Rush Medical College.
 Regent and one of founders of The American College of Surgeons.
 Originator and editor of the volume on Surgery in American Year Book series; also of *Surgical Clinics*.
 Honorary member of several foreign surgical and scientific societies.
- Education:** Graduated at age of twenty-two from Rush Medical College.
 For eighteen months an interne in the Cook County Hospital.
 Practiced medicine and surgery with Dr. Edward W. Lee for two years.
 Subsequently spent twenty months studying in Germany.
 Granted the Lartare medal by the University of Notre Dame in 1902.
 Granted LL.D. degree by the University of Illinois, 1905.
 Granted D.Sc. degree by the University of Sheffield, England in 1908.
- Source of Eponym:** Chapter on The Surgery of the Veriform Appendix in Keen's Surgery, Phila., Saunders, 1913, vol. 6.
- Other Writings:** Murphy wrote voluminously, his writings appearing in current journals and surgical textbooks. (See index library of Surgeon Generals Office.)
 Murphy was one of the first to recognize the importance of early diagnosis and early operation for acute appendicitis. He did pioneer work on the surgery of the gall bladder, alimentary tract, blood vessels, chest, bones and joints.
 It has been said "there is not one branch of general surgery which has not profited by his genius."
- Discussion of Eponym:** Five special tests of value in differential diagnosis were proposed by Murphy; first percussion (kidney); hammer stroke percussion (gall bladder); deep grip palpation (gall bladder); piano stroke percussion (free peritoneal fluid); and comparative bimanual examination (moderate degrees of rigidity).
 Murphy's name is associated with still other diagnostic and therapeutic measures. See also the Murphy button; the Murphy drip.
- Points of Interest:** "The personality of John B. Murphy was so brilliant, so striking, so forceful and intense, and still so attractive, that all who came in contact with him instantly recognized the presence of a remarkable man." (Ochsner.)
 "Among those who knew him well he was admired and deeply respected rather than loved. Except to a very few he was not genial nor responsive in friendship . . . Murphy was beyond question the greatest clinical teacher of his day, anyone who listened to him can never forget the experience." (Moynihan.)
 Murphy conducted a clinic for students and practitioners which became world renowned and his great ability brought to him a stream of rare and difficult cases.
 Murphy was faithfully aided in his researches by his wife (Jeanette C. Plamondon). Mrs. Murphy anesthetized all of the animals used in the extensive experiments on bowel anastomosis and at all times acted as assistant and companion.

CHAPTER CXXVI
THE SURGERY OF THE VERMIFORM APPENDIX¹

By JOHN B. MURPHY, M.D.,
CHICAGO.

And, finally, attention is called to one other method. It is the most simple and should be used by every careful examiner. The simultaneous palpation of the two sides of the abdomen is a method which, where there is acute inflammation, offers greater resistance to the examining hand. We palpate first the healthy side and then the other, and see quite a difference, especially in typical cases, but Murphy has pointed out and proved by clinical results during the past twenty years (since 1889) that decidedly more information is gained when both sides are palpated simultaneously. Compare the way in which the examiner's left hand sinks into the patient's iliac fossa to the lessened descent of his right hand on the side of the inflamed appendix. The difference is grossly apparent in the typical cases. So it is with the slightly involved appendices, those cases with slight recurring attacks, the atypical cases, that this test is most serviceable. An equal pressure on the two sides at the same time, "comparative bimanual examination" will show a difference which, with practice, is discernible in practically all cases where there exists an acute pathologic condition within or around the appendix.

The symptoms of acute appendicitis are as follows, and occur practically always in the same order:

- (1) Pain, primarily in the epigastrium and later at the site of the appendix.
- (2) Nausea or vomiting usually coming on a few hours after the onset of pain and only repeating the attack a few times. It never precedes the pain.
- (3) Local sensitiveness and muscular rigidity over the site of the appendix, showing markedly when contrasted with the opposite side.
- (4) Elevation of temperature, coming on three to twenty hours after the onset of pain.
- (5) Leukocytosis is present in about 97 per cent of the cases. When absent, there may be a marked elevation of temperature.

FIG. 34. Title page of book and page containing Murphy's description of bimanual comparative abdominal palpation.

QUESTIONNAIRE

1. What constitutes the floor or lower boundary of the abdomen?
2. Bound the pelvic inlet.
3. What is the pelvic diaphragm? Its action?
4. Why is the pelvic floor of interest to the abdominal surgeon?
5. Describe the relation of the rectum to the peritoneum.
6. What peritoneal abnormalities may be discovered by rectal examination?
7. What is meant by "a transcelomic malignant transplant"?
8. Give a technic for the rectal digital examinations.
9. What various positions may be employed in making a rectal examination?
10. Describe the Sims' position. The lithotomy position.
11. Describe the method for passing a sigmoidoscope.
12. What are the normal curvatures of the rectum?
13. What structures normally felt upon rectal digital examination may easily be mistaken for tumors?
14. What are the advantages of rectoabdominal palpation?
15. Explain why foreign bodies passing through the anus may reach higher levels within the enteral canal.
16. Name the evidences obtained through alvine discharges of biliary disease, pancreatic disease, ulceration within the bowel wall.
17. What is a pelvic peritoneal hernia?
18. How may small bowel be injured in the treatment of procidentia recti?
19. What is meant by rectopexy? By archocele?
20. Is the peritoneal cavity an open or a closed space?
21. What is the pathogenesis of pneumococcus peritonitis?
22. What is the most striking contrast between the walls of the upper and lower divisions of the trunk?
23. Give the derivation of the following words: chest, thorax, abdomen, belly, venter.
24. What is the ventriculus?
25. Name the muscles of the abdominal wall.
26. Give a list of the skeletal muscles of the body wall which may show reflex muscular rigidities due to intra-abdominal disorders.
27. With what muscles must an operator deal in entering the abdominal cavity at various points?
28. Name the muscles covering the abdominal cavity on its (a) anterior and lateral walls, (b) its posterior walls, (c) its floor, (d) its roof.
29. Trace some of the nerve pathways through which abdominal organs are connected with skeletal muscles.
30. What cord levels are connected with the prevertebral ganglionic chains of the thoracolumbar division of the involuntary nervous system by means of the white rami communicantes?
31. Through what cord levels are afferent stimuli arising from the ureter in renal colic chiefly relayed to skeletal structures?
32. From what cord levels do the muscles of the upper extremities receive their motor neurones? The lower extremities?
33. What muscles connect the lower extremity with the pelvic girdle and trunk?
34. What skeletal muscles are in reflex association with afferent stimuli arising from the central portion of the diaphragm?
35. What skeletal muscles are in reflex association with peripheral portions of the diaphragm?

36. Give the innervation of the muscles reflexly associated with abdominal organs. What is the posture assumed from the continued contraction of each of these muscles?
37. Describe the technic of an examination for abdominal rigidity.
38. What is meant by "comparative bimanual abdominal palpation"; its advantages?
39. What is meant by "palpation of the indrawn abdominal wall"?
40. What is meant by "palpation with the depressed costal arch"?
41. What is the diaphragmatic phenomenon?
42. What is Litten's sign?
43. What is the cause of dyspnea as observed with acute biliary colic?
44. What abdominal organs may give rise to reflex spasticity of muscles of respiration?
45. Give four methods by which spastic contraction of one side of the diaphragm may be detected.
46. Since reflex spasticity of muscles of respiration may be caused by both intra-abdominal and extra-abdominal disorders, how can the determining factor be ascertained?
47. What is meant by the "subinguinal syndrome of renal colic"?
48. What are the effects of spasm of the cremaster muscle?
49. What is the significance of cremaster spasm in a differentiation of acute appendicitis from renal colic?
50. What is the ureteral cutaneous triangle of the thigh?"
51. State the postural effect of spasticity of the quadratus lumborum muscle.
52. What is the relation between spasm of the iliopsoas muscle and acute appendicitis?
53. What is the psoas test?
54. Explain the muffled voice often noted during acute attacks of colic.
55. How can intra-abdominal muscles reflexly effect the eye or ear?
53. What are viscerovisceral phenomena? Visceromotor phenomena?
57. Differentiate a visceromotor reflex from a peripheral nerve irritation. Give nerve pathways for example of each.
58. How is the abdomen supported by the skeleton?
59. What bones belong exclusively to the abdominal division of the trunk?
60. Distinguish between the skeletal supports and the skeletal protections of the abdomen.
61. What bones serve directly to protect abdominal organs?
62. How many ribs, or parts of ribs, overlie the abdomen?
63. What percentage of the abdominal cavity is covered by bone?
64. How closely do the lower ribs approach the iliac crests?
65. What abdominal viscera are normally palpable?
66. What is meant by "mesenteric ileus"?
67. What is the intercostal angle?
68. Of what importance is the intercostal angle to the surgeon?
69. Why is the intercostal angle found in visceroptotic individuals?
70. What is the relation between incomplete rotation of the intestine and congenital visceroptosis?

No. 3

A CLINICAL CONSIDERATION OF INTESTINAL OBSTRUCTION*

C. JEFF MILLER, M.D., F.A.C.S.

NEW ORLEANS, LA.

THE salvation of human life," says Lord Moynihan of Leeds, "is a greater thing than the establishment of a convincing, irrefutable clinical diagnosis," and Arthur Curtis remarks, in another connection, that "it is better to have a less accurate diagnosis and a more favorable prognosis." There are possibilities of danger in these aphorisms, I admit, but if they were steadfastly borne in mind we should see a prompt reduction in the mortality of at least one clinical entity. I have reference to intestinal obstruction, a condition in which the lowest mortality is achieved not by the conservative surgeons who operate only on definite diagnoses and for whom, ordinarily, we have only praise, but by that other group of surgical enthusiasts whose resort to the knife is immediate and for whom, ordinarily and properly, we have only condemnation. Their craftsmanship may be dubious, their surgical judgment is unquestionably dubious, but in this one contingency, at least, we would do well to emulate them, for they lose the fewest patients from this deadly disease.

For surgery is the one treatment, the only treatment, for intestinal obstruction. Exploration is warranted on the barest suspicion that it exists. A properly made exploratory incision seldom does harm, and surely it is a better thing to open the abdomen and find nothing than to open

it after days of delay, when a moribund patient carries his diagnosis on his face, and find pathology which, because priceless time has been lost, no amount of surgical judgment and no exhibition of surgical dexterity can possibly remedy.

The logic of immediate operation is apparent if we reflect upon the true nature of intestinal obstruction. Its pathology is purely mechanical in origin, and mechanical faults can be rectified only by mechanical means. The spontaneous formation of a fecal fistula or the spontaneous correction of the obstruction are possibilities too remote to be seriously considered. The patient who is not operated on is going to die. He may die anyway, he will certainly die if surgery is delayed too long, but that is no reflection upon surgery. It is, however, a decided reflection upon the quality of the surgical judgment that deferred its performance.

You know the incidents of the sorry story so well that I need not linger upon them. The patient, seized with abdominal pain, resorts to purgation, the great cure-all of the laity. When he grows no better he calls in the medical man, who experiments with further purgation, with opiates, with fine-spun laboratory tests and other time-consuming measures. Eventually the surgeon is summoned, the surgeon who is quite as prone to delay as is his medical confrère but who escapes a good deal of opprobrium because in most instances

* Read before the Pan-Pacific Surgical Congress, Hawaii, August 19, 1929.

he is not in at the start. Finally operation is resorted to, and operation, late in this disease, is most often the gesture of despair. It is done, as Lincoln Davis vividly says, not with any special hope of saving the patient but simply because the ethics of the profession does not permit one to operate for "a batting average." Even in the early stages of intestinal obstruction the patient is much sicker than he looks, and in the late stages he is plainly so ill that no medical knowledge is necessary to assert that here is a human being beyond the hope of succor.

At this point I am minded to refer, although with considerable trepidation, to a tendency widely current in this age of research, the tendency to lose sight of the clinical aspects of this condition, as of many others, under the weight of laboratory details. I hope that you will not misunderstand me. I have only the highest praise for the work that has been done by such investigators as Whipple, Stone, Scholefield, Hermann, Gatch, Trusler, Ayres, Foster, Haden and Orr. It has been of incalculable aid in determining pathology and in establishing a therapeutic rationale, and almost without exception the men who have done it have preached and taught that nothing which they have discovered, nothing which they hope to discover, can obviate the necessity for speedy operation in every instance of intestinal obstruction. But, consciously or unconsciously, much of their work has been distorted and made to seem a justification for procrastination. Certain of the profession, at least, have tended to dwell on the experimental work done on laboratory animals, on the exact nature of the toxins elaborated in the bowel, on the precise causes of death, forgetting that in the final analysis the only important aspect of this disease is its clinical aspect. Our chief concern must ever be with the damaged bowel wall. A knowledge of the lethal agents present may be important, but surely it is more important to dwell upon the early clinical manifestations, the

prompt recognition of which will remove any necessity for studying their terminal results. Moreover, conditions produced experimentally in animals by no means parallel conditions actually present in humans, and it might be well, at least occasionally, to pay less attention to mice and more attention to men. Finally, in this disease preeminently, the pathology of the living is a study of considerably more value than the pathology of the dead, and a deeper concentration on it would undoubtedly mean that the autopsy room would furnish us with fewer examples of it.

The protean character of intestinal obstruction is very often overlooked. It is anything but a simple disease. It is true that in the beginning, unless there is immediate circulatory damage, the picture is one of a simple blockage of the fecal current by some mechanical obstruction. But once the pathology has lasted an appreciable time, even those cases which have begun as simple obstructions merge promptly into the vascular type. Then, with interference to the circulation, come damage to the bowel wall, gangrene, necrosis, even perforation with consequent peritonitis, and the elaboration of a toxemia which is perhaps the most serious feature of all. In short, intestinal obstruction is a disease which remains localized only a very little while, and in which constitutional changes of the gravest sort come to pass within an amazingly short space of time.

It follows, then, that in a disease of such potential gravity the promptest diagnosis and treatment are essential. But this is not as simple as it sounds. The symptoms and physical signs are inconstant and variable, and diagnostic methods are far from conclusive. In practically no early case is the full classic syndrome apparent, and, as a matter of fact, when it does appear the patient is very likely to be near his death agony. The surgeon who operates for obstruction only when the diagnosis is confirmed by

the full complement of symptoms may achieve an enviable reputation for diagnostic acumen, but it will be in the autopsy room, for he will have few living patients to his credit.

Pain, the earliest symptom and the most constant, is, I would say, the inevitable concomitant of intestinal obstruction. I would remind you, however, that the abdominal viscera are largely insensitive, even when they have become pathologic, and that a proper comprehension of the mechanism by which pain is produced is even more essential in this case than it is in most other abdominal diseases. Only in rare instances is exact localization possible. The pain most usually originates vaguely about the umbilicus, less often in the epigastrium, but finally the whole abdomen is implicated. The character is quite definite. If the mesentery is involved the pain is continuous from the outset. Otherwise it begins in a colicky and intermittent fashion, and it becomes continuous only when the disease has progressed beyond the first stages. Be not deceived, either, by its subsidence. That in itself may be a most misleading thing, for it may portend the development of gangrene and not the abeyance of pathology.

Vomiting is by no means the constant symptom which pain is. In obstruction of the small bowel it is present from the start, at first as a reflex phenomenon, later because of a hypersecretory activity of this normally very active portion of the intestine, an activity which may be increased, aside from the obstruction, by misguided efforts to force fluids by mouth. In colonic obstruction, on the other hand, vomiting is usually a late symptom and it may never appear. At first the vomitus consists of gastric contents, then of bile-stained fluid, and finally of true fecal matter, unless this latter development is prevented by the fact that the small bowel obstruction acts upward as well as downward. There is no more misleading symptom than this same fecal vomiting,

and I am in hearty accord with the writers who contend that the term should be removed from the vocabulary of intestinal obstruction. It is absolutely diagnostic of obstruction, but it is likewise absolutely prognostic of impending death, and for my own part, I have never seen a patient recover in whom true fecal vomiting had been exhibited.

Since the very term intestinal obstruction carries with it the implication of a stoppage of the fecal current, it might be expected that absolute constipation would be a definite and immediate symptom. This is far from the truth. The higher the obstruction, the less likely is constipation to be evident promptly, and it must be remembered, too, that in intussusception and mesenteric thrombosis, frequent thin, watery, blood-stained stools are more likely to be the rule. It is often urged, in this connection, that, as a diagnostic measure, two enemata be given, the first to empty the bowel, the second to demonstrate the obstruction. Aside from the fact that this is a time-consuming procedure, it may not serve the purpose at all, for in a high obstruction even mechanical means may not fully or promptly empty an overloaded lower bowel. Moreover, unless there is complete relief of symptoms simultaneously, the mere passage of feces cannot be accepted at its face value. More to the point is the suggestion of Codman, that digital rectal examination be done routinely, which will reveal an empty rectum in which the walls crowd around the finger, while above is a sensation of tremendous intra-abdominal pressure. Quinn emphasizes the same point, declaring that it is more important to insert a finger in the lower end of the alimentary tract than a thermometer in the upper.

Distention is the promptest and most conspicuous physical sign, but again it is an inconstant manifestation and a late one, except in volvulus of the sigmoid, when it may be prompt and alarming. Tenderness is never apparent until after distention

has occurred. Rigidity is evident only when localized peritonitis has set in, and in marked toxemia, when the muscular defense is lacking, it may not appear at all.

Visible peristalsis is pathognomonic, but it can be demonstrated only occasionally and late. Audible peristalsis, however, is a different matter, and many agree with Deaver that auscultation of the abdomen, either with the naked ear or with the stethoscope, should never be omitted. In the early stages, as he points out, there is a hyperactive, noisy, whirring peristalsis, which ceases absolutely at the point of obstruction. In the second stage there is a high-pitched, bell-like tinkle, due to gas and fluid moving in a tubular space. And in the final stage there is the "ominously silent" abdomen, in which all activity has ceased and in which the only sound is the pulsation of the aorta. Bayley of Los Angeles describes another sign which I have nowhere else seen mentioned. He claims that in certain early cases, as the result of free fluid under tension, the heart sounds may be transmitted through the abdomen and heard in any or all of its four quadrants. Unfortunately, while this sign is almost pathognomonic, it is inconstant and is therefore of value only in conjunction with other findings.

Elevations of temperature, as would be expected in a condition that is not primarily inflammatory, are never apparent in the early stages of intestinal obstruction, at which time normal or distinctly subnormal temperatures are the rule. The pulse, on the other hand, tends to rise speedily, and this fact, taken in conjunction with the low temperature, is an important diagnostic point. Shock is apparent from the first when the circulation is affected, is always associated with distention, no matter what the primary cause of the obstruction, and is always a part of the toxic picture of the final stages. The blood pressure of these patients, therefore, must be carefully watched from the outset.

A routine urinalysis is, of course, impera-

tive, but otherwise the laboratory offers small aid, except of a negative kind, in the early case. The blood count, unless the circulation is affected, remains within normal limits until inflammatory changes have set in. Continued vomiting eventually produces definite body changes, the most marked of which is a disturbance of the blood electrolytes, depending largely upon the location of the obstruction. Blood studies will often show a loss of chlorides, a rise in the non-protein blood nitrogen, and a rise, sometimes to extraordinary figures, of the CO_2 combining power of the plasma. These changes, however, occur too late to be of diagnostic value, and there is small ground for the suggestion, occasionally advanced, that the indications for operation in intestinal obstruction should be based upon repeated tests of this character. Renal damage is evident late, not only in the laboratory findings, but in the lessened fluid output, sometimes amounting to actual anuria. Indeed, in the absence of an adequate history, a patient in the last stages of intestinal obstruction could, from the clinical picture, quite logically be treated for uremia, and I have more than once seen this happen, the true lesion being discovered only at necropsy.

Although I am strongly opposed to the administration of a barium meal in any suspected intra-abdominal pathology, I am heartily in favor of the use of the x-ray as advocated by Case of Chicago. The patient is examined, preferably in the standing position, and the relative levels of gas and fluid are studied as soon as the plate can be developed. This procedure takes but a short time, and in the hand of a skilled roentgenologist it can be very valuable in the elucidation of obscure cases.

The diagnosis of intestinal obstruction, it is clear, must be made with a very confusing array of symptoms and signs, and with very uncertain methods of diagnosis. Yet it must be made promptly, for, as we have said, this is one disease in

which literally moments count, in which the development of the classic syndrome is an almost certain sign that the patient has passed beyond mortal aid. What should be our procedure in this grave hour? First, there must be a careful history, with special reference to past surgery and similar past attacks. Intestinal obstruction is very often a bolt from the blue, but it may have definite antecedents, the chief of which is a story of previous surgery especially for pelvic disease or for appendicitis with drainage, for these two types of operation are estimated to furnish from 20 to 40 per cent of all intestinal obstructions. The history of the present attack, with the character and chronology of the symptoms, is equally important. Then must come a physical examination sufficiently general to eliminate intercurrent disease, sufficiently detailed to investigate all areas of the abdomen, all hernial openings, all rectal pathology, and, in a woman, all pelvic pathology. A urinalysis and a blood count should be routine, and blood may be taken for chemical study, though, as I have said, there is no justification for delaying operation until this type of investigation can be concluded. Finally, all of the findings must be carefully weighed and evaluated, there being always, well to the fore, the recollection that any patient suffering from intra-abdominal distress may be suffering from intestinal obstruction, and that the possibility is not such a remote one at that.

The important thing is to recognize that an obstruction is actually or possibly present, or that some other definitely surgical intra-abdominal pathology which resembles it is actually or possibly present. A differential diagnosis, while desirable, is not essential, for the reason that if cardiac, pulmonary and renal disease be eliminated (and their elimination is not difficult) any other intra-abdominal condition which can be confused with intestinal obstruction is amenable only to surgery. It is a safe rule to follow that any ab-

dominal pain which lasts more than six hours in a previously well person, especially if it is accompanied by any of the signs and symptoms we have enumerated, and if it is not permanently relieved by a single small dose of morphia, is evidence of a pathology which can be corrected only by operation.

The location and type of the obstruction are likewise of little moment. The small bowel is more likely to be implicated than the large, and it is Carson, I think, who points out that the higher the obstruction the more constant the symptoms, especially vomiting, while the lower the obstruction the more constant the signs, especially meteorism. Again, obstructions of the small bowel are more likely to exhibit a sudden onset, almost the only exception being volvulus of the sigmoid, while obstructions of the large bowel are more likely to present a previous history of digestive disturbance. Herniae, at least of the external variety, carry their own diagnosis. The history of a previous operation is highly suggestive of the existence of bands or adhesions. Impacted gallstones are always preceded by a typical history of digestive disturbance, and the same history, plus loss of weight, suggests malignancy of the large bowel. This is probably the most common cause of obstruction in the aged, and it almost always presents itself as an acute obstruction superimposed upon a chronic one. Rapid and enormous distention, sometimes to the point of respiratory embarrassment, is pathognomonic of volvulus of the sigmoid. Mesenteric thrombosis is prone to occur in middle-aged individuals, more commonly men, of a phlethoric type, and to be associated with immediate shock and a raised leukocytosis. All of this, however, though interesting and gratifying from the standpoint of diagnostic acumen, is beside the point. The conviction of intestinal obstruction, or the suspicion of it, is the one thing that is needful.

While the diagnosis is being considered,

the important thing is to stay one's therapeutic hand, to restrain one's "philanthropic propensities." This is not always easy. An anguished patient and an anxious family may be insistent for relief, but this is one set of circumstances in which nihilism is true wisdom. Opiates serve only to mask symptoms, and purgatives, as Haggard well observes, simply "compound the felony of delay." By increasing a peristalsis that is already too active they serve to augment the distention of the overtried bowel, and to increase its bacterial activity, while if the stomach, and very properly, refuses to tolerate them, the body, as the result of increased vomiting, is still further depleted of its fluids.

At operation three principal problems arise: the correction of the actual obstruction, the management of the damaged bowel, and the combating of toxemia. In most early cases, unless an associated paralysis complicates the issue, simple relief of the obstruction is sufficient, but in advanced cases, as we have already pointed out, considerably more is involved than the interruption of the fecal current. Moreover, we must guard against harming the patient by the very means we employ to relieve him: in the late stages of the disease the mere relief of the obstruction is fraught with danger, permitting, as it does, a rush of toxic substances into the hitherto intact bowel or the return of the circulation to an already necrotic loop. Finally, even if the patient be relieved of his toxemia by drainage of the bowel and other adjuvant measures, he may still die of the unrelieved primary obstruction which, in his critical condition, it would be fatal to attempt to rectify.

It is plainly impossible to speak categorically of a disease in which each case must be judged upon its own merits. For working purposes, however, we can advantageously employ Sir William Taylor's very logical classification of cases, based, as is so much in this dread disease, on its duration. The condition of the patient is the determining

factor in deciding upon the type and extent of the procedure. In the first group he is seen early and operated on promptly; his condition is good, and simple relief of the obstruction most often suffices for a cure. In the second group he is seen later; his condition is still fairly good, but toxemia is either an actual or a strongly probable complication, and drainage of the bowel is done in addition to relief of the obstruction. In the third group he is seen late, indeed often he is frankly moribund, and his toxemia is so overwhelming that the primary obstruction is lost sight of. Operation is done only because even a dying patient deserves his chance for life, slender though that chance be. Drainage of the bowel, through the first presenting loop of jejunum, is the only procedure warranted. If the patient survives, and most often he does not, the primary obstruction can be dealt with at a later date.

The high mortality reported after enterostomy, either alone or combined with other procedures, is no more an argument against it than is the high general mortality of intestinal obstruction a reflection on its surgical management. It is employed only in frankly bad risks, and where control series have been fairly studied, a definite reduction in the mortality has always been noted. Moreover, jejunostomy, if done by the Witzel technic, escapes the disadvantages usually attributed to it, the loss of digestive fluids and the development of fistulae which require later tedious closures.

As to other procedures, invagination and plication of gangrenous or suspicious areas of the bowel wall is a dangerous operation (indeed, a gangrenous bowel, whether drained or undrained, should never be left within the abdomen) and its apparent conservatism results in a higher mortality, in most instances, than the frankly radical procedure of resection. The latter, many surgeons believe, is indicated in every case in which distention and toxemia, with their consequent paraly-

sis, play a part, but except in very high obstructions, when loss of the digestive fluids would be a serious consideration, the two-stage operation is better than immediate anastomosis.

Operation for intestinal obstruction, I need scarcely point out, is anything but a simple procedure. The utmost manual dexterity is necessary, for, as Bunnell says, every manipulation, necessary or unnecessary, is "a shove nearer the grave." The least that can be done is the safest for the patient. It may be a highly satisfactory thing to complete a perfect operation, but it is a highly unsatisfactory thing to complete it on a corpse, and these patients have a disconcerting way of dying on the table, under one's very hands. In short, surgical judgment here comes into its own. To speak very bluntly, only an experienced surgeon has a right to undertake operation for such a condition as this, in which craftsmanship means much, in which knowledge means much, but in which wisdom, which is the application of knowledge, means even more. Like Lord Moynihan, I stand amazed at the ready acceptance by patients "of the eager ministrations of incompetent operators," when it would be quite as easy to secure adequate skill and experience, both of which are here taxed to the limit.

In the average case of intestinal obstruction there is no time for the rehabilitation of the patient, at least as we commonly understand the term. Two things, however, must not be omitted. Gastric lavage must be instituted and must be repeated until it returns clear, and it is a wise precaution, too, to leave the tube in situ during anesthesia, lest, when the glottic reflex is obliterated, the patient drown in his own secretions, or lest, later, he develop an aspiration pneumonia. Parenthetically, I might add that in spite of all the arguments against it and in spite of all the advantages claimed for other types, my own preference is still for general anesthesia, even for ether, admittedly the least

auspicious of them all. In both local and spinal analgesia, it seems to me, the inevitable prolongation of the operation and the inevitable additional manipulations and trauma, which increase the shock of an already badly shocked patient, outweigh all the advantages claimed for them.

In the second place, hypertonic salt solution must be promptly given, preferably by infusion, to restore the fluid balance and to replace the lost chlorides, if this loss can be demonstrated; otherwise isotonic saline, as suggested by Selling Brill, may be employed instead. The use of saline, altogether with infusions of glucose and insulin, is continued after operation as long as the indications, based on the patient's clinical condition and the laboratory findings, warrant it. Other postoperative measures are employed according to the exigencies of the special case.

One or two other therapeutic measures might be briefly mentioned. B. W. Williams and Zachary Cope in England, and Bower and Clark in America, have reported striking results in a limited number of cases by the use of anti-gas serum. Williams first called attention to the striking likeness between gas gangrene and the terminal toxemia of intestinal obstruction and suggested that this similarity might be due to the actual presence of the toxins of *B. Welchii* in the fecal contents above the obstructed bowel.

Wagner in 1922 first pointed out the application of the effect of spinal analgesia in increasing intestinal peristalsis, and since that time this measure has been employed sporadically to overcome the paralysis of intestinal obstruction. The results have been very uneven and the issue has been clouded by the bad effects inherent in this special agent. Working from these premises, Ochsner and Gage, of the Department of Surgery of Tulane University, have recently suggested the substitution of splanchnic analgesia for spinal, on the ground that it is free from the disadvantages of the latter type, and

that, if the method of Kappis be employed, it is not necessary to open the abdomen to administer it. Their claim is that in those cases in which paralysis continues after relief of the obstruction, with or without drainage of the bowel, the mechanism being the inhibition of intestinal motility resulting from impulses passing by way of the sympathetics, this type of analgesia will overcome the paralysis by blocking the reflex and thus abolishing the inhibition. It must, of course, be employed only after mechanical relief of the obstruction. Prior to that time there is present a hyperperistalsis, and there is no advantage to increasing it. If the clinical application proves as satisfactory as the experimental work has been, we have reason to hope that we shall have in our possession a most valuable weapon with which to combat the hitherto invincible paralysis of intestinal obstruction.

The conclusion of the whole matter is that the prognosis of intestinal obstruction, as well as the rationale of its treatment, is absolutely dependent upon the time element involved. The mortality

rises approximately 1 per cent with each hour of procrastination, and any mortality over 10 or 12 per cent can be charged only to delay. The death rate, which is popularly quoted as 30 or 40 per cent, actually is 55 or 65 per cent, and we are only stultifying ourselves when we refuse to face the true figures. In fact, it is very little lower today than it was forty years ago, when Fitz and Senn did the pioneer work in its study, and when medical treatment for forty-eight hours was the accepted rule. Medical treatment is not the rule today. Surgery is universally admitted to be the only rational and possible treatment. The trouble is, however, that in a lamentable number of cases our practice does not accord with our theory. And it is this sorry state of affairs, with its resulting almost criminal mortality, which must be my excuse, if excuse be needed, for having presented to you in this paper a subject to which, I am quite aware, I have added nothing new, but which, I am likewise certain, can be clarified and elucidated only by ceaseless iteration of the tragic facts of the case.

STUDIES IN THE EMBRYOLOGY OF BONE DEVELOPMENT*

LEONARD ZWEIBEL, M.D.

NEWARK, N. J.

BONE development in the human embryo can best be understood by actually seeing the bones in situ in the various stages of development. The method used to show these changes embodies two principles, one the depigmentizing of the soft tissue, and the other, the staining of the bone tissue.

The depigmentizing was accomplished by a prolonged process through various strengths of potassium hydroxide, and the standing of the bone was done with an alcoholic extract sodium alizarin sulfonate in a 1 per cent potassium hydroxid.

Before the actual process of depigmentizing is employed, a preliminary bleaching, fixing and hardening of the material is necessary. The material, as soon as obtained, is best put into 70 per cent alcohol. Upon arrival in the laboratory, it should immediately be transferred to iodine alcohol, which is prepared by adding enough crystals of iodine to 95 per cent alcohol to impart a deep iodine color. After remaining in iodine alcohol for two days, the material should be then placed in 2 per cent aqueous potassium bichromate solution and left there in the dark room for thirty-six hours. Next, after washing in cool, running tap-water for two hours, the material is placed in 50 per cent alcohol and left there for three hours; after this, it is transferred to 95 per cent alcohol, in which it is allowed to remain for two or three weeks. During this time, the alcohol is changed as frequently as is necessary in order to keep the alcohol reasonably clear. At this stage in the preparation of the material, it is advisable to hemisect and eviscerate the fetus.

Now the material is ready for depigmentizing. The agent employed is aqueous potassium hydroxid which is changed twice a week. The percentage varies from

¼ per cent for a very young fetus up to 4 per cent for a full term fetus. The best results are obtained when the specimen is kept in the sunlight; the reason for the favoring action of the sun's rays is not determined. The alpine rays can be excluded as a factor, because they do not penetrate the glass jars in which the specimens are contained; apparently the heat of the sun's rays is a very important factor, as determined by the fact that depigmentizing proceeds more rapidly in an incubator at 37.5 c. than at room temperature. However, it has been determined that there are bleaching rays in the sunlight which penetrate the glass of the containers, and are important adjuvants to the heat in the bleaching process.

When the depigmentation has advanced to the point that the ribs of the fetus become readily visible, the specimen should be stained. The basis of the stain is a saturated solution of sodium alizarin sulphonate in 95 per cent alcohol. Such a saturated solution has a golden color quite similar to that of the dry powder. The final staining reagent is prepared by adding the saturated alcoholic extract of the dye, a little at a time, to a 1 per cent potassium hydroxid solution, until a deep Burgundy wine color is obtained. The time required for staining varies from six to twenty-four hours, depending upon the age of the fetus. After the staining process is complete, the fetus is washed in cool running tap-water for one hour. Then the specimen is placed in a mixture of 5 per cent glycerine and a percentage of potassium hydroxid equivalent to that used for the initial depigmentation of the specimen. After remaining in this solution for several days, enough of the stain will have dissolved out of the soft tissues of the fetus to rather markedly color the solution. (From now

* Prize Thesis, from the Department of Obstetrics and Gynecology, Long Island College Hospital, Brooklyn, N. Y., June, 1929.

on, the solution is changed at about two-day intervals, the amount of alkali at each change being very gradually reduced,

prevent fungus growth (in one specimen, there were several colonies of *penicillium glaucum*, a black mould, growing on the

FIG. 1.

and the glycerine somewhat more rapidly being increased in amount. When a concentration of 25 per cent glycerine is attained, the hydroxid should be discontinued; at this stage the depigmentation should be nearing completion. After seven days in 25 per cent glycerine, the fetus is transferred to a 28 per cent ammonium hydroxide solution and left there for two days; then the specimen is put back into 25 per cent glycerine, and at weekly intervals is transferred to increasing percentages of glycerine until a concentration of 100 per cent is attained. After several changes in 100 per cent glycerine, the specimen is mounted in this latter reagent, to which is added a crystal of thymol to

100 per cent glycerine to which thymol had not been added).

Larger fetuses require some variation in the described technic. Usually after the fifth month there is much subcutaneous fat which markedly interferes with the clearing of the specimen, and requires special technic which is best employed at the end of the hardening process, before using the hydroxid. This variation consists in changing from 95 per cent alcohol to acetone, in which latter reagent it is left for several days; then to an acetone-xylol mixture and gradually increasing the xylol until 100 per cent xylol is used for several hours to several days, and then working backwards through xylol acetone to alcohol. This

method usually clears the fat, but a large amount of shrinkage of the specimen is unavoidable.

The basis for development of the bony tissue, of which there are two types, is embryonic connective tissue. In one type

FIG. 3. Roentgen-ray of three months' fetus with resistance.

The process of depigmentation and staining is a time-consuming one. The smallest embryo, of ten to twelve weeks, requires about three months, and progressively with the increase in age of the fetus the time element is lengthened so that a full term fetus requires approximately two years for completion.

In the completed specimen, the entire bony skeleton system is visible, as well as the cartilage that has some calcium in it. One can easily distinguish cartilage from bone, the bone taking a definite red opaque color and the cartilage a brownish translucent hyaline-like appearance. The skull bones especially are brought out very distinctly. As early as the third month the tympanic ring can be seen to be definitely calcified. The ossification centers are easily traced and studied, and a truer conception of the gross difference between the cartilage and membrane bones is had from these stained specimens, than can be obtained from the finest roentgen plates.

FIG. 4. Four months' fetus, stained. Length prior to preparation 17 cm.

of development cartilage precedes the bone and in the other, membrane formation precedes the bone. In intramembranous ossification the calcium salts are deposited in ordinary embryonic connective tissue. In intracartilaginous ossification, hyaline cartilage first develops in the same general shape as the future bone and the calcium salts are afterwards deposited within the mass of the cartilage.

The membrane bones, for example many

of the flat bones of the skull and face, are ossified by bundles of connective tissue fibers becoming impregnated with calcium

teum, where the osteoblasts are numerous, thus causing growth and enlargement of the bone.

FIG. 5. Three months' fetus, stained. Length 9 cm. prior to preparation. Showing osteochondritis and poor bone calcification.

salts. These calcified bundles are calcification centers. These bundles are clearly demonstrated, especially in the younger of the stained specimens, as shown on the photographs and roentgenograms. In each of these areas, the cells increase in number, the tissue becomes very vascular and some of the cells become more oval with distinct nucleus and considerable amount of cytoplasm, then arrange themselves in single, fairly regular rows along the bundles of calcified fibers. These cells are known as osteoblasts and the whole tissue is known as osteogenic tissue. Under the influence of the osteoblasts, a thin layer of calcium is deposited between the osteoblasts and the calcified fibers. In this way true bone is formed. On the inner surface of newly formed bone, osteoclasts cause dissolution, while new bone is being formed on the outer surface especially under the perios-

FIG. 6. Enlargement of lower extremity of fetus in Figure 5, showing osteochondritis in tibia and lack of calcification in fibula.

Intracartilaginous ossification, physiologically, is similar, but for the fact that it is performed by cartilage, shaped similarly to the future bone. The ossification center is usually single in these bones (the sternum is one exception, having several centers of ossification). The ossification center is in the center of the bone, especially as seen in the long bones, and the osteogenic tissue pushes in both directions toward the end of the cartilage (in the long bones towards the epiphysis). Summarizing, ossification in cartilage consists of the following stages: (1) multiplication of cartilage cells; (2) calcification of the cartilage; (3) absorption of the

calcified cartilage, and (4) deposition of true bone, that is, calcified fibrous tissue, round cells and osteoblasts which have

certain amount of calcium carbonate is precipitated in the matrix around the osteoblasts. The identical ferment is found

FIG. 7. Roentgenogram of three months' fetus, superimposed over normal pelvis roentgenogram.

invaded the calcified cartilage from the marrow.

The lime salts are stored in the bones the same as glycogen is stored in the liver and can be taken out of bone if needed by other part of body in the same manner. The calcium is carried by the blood stream to the bone. An old theory was that the maternal blood caused supersaturation of the calcium in the fetal blood and this caused the calcium to be deposited in the bone tissue of the fetus, because circulation in this region was more sluggish. This theory, however, was not substantiated in any way, because there was no scientific reasoning behind it.

An important rôle in carrying calcium salts to the bone is played by a hexose monophosphoric ester, which forms soluble salts with the calcium. This hexose monophosphoric ester is a normal constituent of circulating blood and in turn depends on the glucose of the blood. Under the action of a ferment which is present in ossifying cartilage, this calcium salt is hydrolyzed and calcium phosphate with a

FIG. 8. Roentgenogram of five months' fetus, superimposed over normal pelvis roentgenogram.

in the intestines and kidneys. In the gut it joins the calcium, phosphate and sugar to form the soluble calcium hexose monophosphoric ester, and in the kidney it may be responsible for the secretion of the phosphate in excess.

The manner in which these various inorganic constituents are combined in bone, whether chemically or physically, is not known, but it is probable that the calcium carbonate and calcium phosphate are united, and it is possible that magnesium phosphate is included in the same molecule.

The drain on the mother's calcium and sugar is thus easily visualized. It is interesting in this connection, that after phosphorus poisoning a patient craves sugar, which no doubt is due to loss of body sugar in eliminating the phosphorus.

The true etiology of congenital variations and anomalies has not as yet been ascertained with any degree of exactness in most cases. A few years ago fright, seeing horrible sights and other superstitions were blamed for congenital defects, especially monstrosities. The conditions recognized as capable of modifying bone development are:

(a) Germinal and prenatal infection with *Treponema pallidum*

(b) Congenital rickets

FIG. 9. Roentgenogram of full term fetus (shrunk by process), superimposed over normal pelvis roentgenogram.

(c) Infarcts

(d) Oligohydramnios

(e) Chondrodystrophia fetalis

(f) Osteogenesis imperfecta

True germinal infection implies that a disease-producing microorganism is carried by the ovum or the spermatozoa and incorporated in the embryo prior to its development. It has been claimed that syphilis may thus be transmitted by the male to the ovum in utero, the mother remaining uninfected by the disease. In prenatal infection the organism must pass the placental barrier. This implies that the fetus becomes infected directly from the maternal blood stream or by continuity of growth of the organism through the placenta. The placental form of infection is not conceded by all observers, but it is reasonably certain that congenital lues can be contracted thus.

Bone lesions of late congenital lues and

acquired lues are distinctly different from those of fetal and early congenital lues. In the early type the disease affects chiefly the ends of the long bones. In late lues, it affects the flat bones with gumma and bone destruction (gumma, necrosis and caries sicca) and bone proliferation (osteosclerosis and osteoperiostitis).

A child with early congenital lues may show the deformity at birth or not until a later date, although infection may be present. The infection in all cases, except germinal, if there is such, is hematogenous.

The *Spirocheta pallida* or treponema of Schaudinn exerts certain effects on the fetal skeleton. The characteristic skeleton lesions are not seen before the fifth month according to Keith, and thus the many luetic miscarriages on the third month of pregnancy would show nothing. However, the picture of the prepared specimen of a third month miscarriage of luetic parentage shows definitely osteochondritis of the tibia (diagnosis confirmed by Dr. Archibald Murray, fetus aged three months).

The osteochondritis here is shown by the abnormal width and irregularity in shape, as well as irregular calcification of the distal end of the tibia and complete absence of calcium in the fibula. Normally a fetus of this size has well-developed bone. According to Hess, tibia and fibula are well ossified at ten weeks. The luetic condition caused the pathology already stated plus poor calcification throughout, making it possible to see on a large scale how the calcification centers appear in the other bones, which normally would have been at those stages about three weeks earlier, because of the delayed calcification. This specimen shows best when compared with the normal specimen of the same age which is shown here. In practically all prematurely born and prematurely stillborn children with congenital lues, luetic bone changes are found. These may be accompanied by skin and mucous membrane changes which appear at the eighth month of pregnancy.

One of the most important anatomical

signs of syphilis is syphilitic osteochondritis which often renders anatomical diagnosis possible, if the other symptoms pointing to lues are absent. When seen, it may be difficult to prove even clinically at times, but it is most always a sign of latent syphilis in such cases. Syphilitic osteochondritis leads to a widening and irregular formation of the zone of calcification which is indistinctly outlined against the epiphysis and sends out jagged offshoots into the latter. This lesion occurs most frequently in the distal end of the femur, then in the tibia and fibula, and then in both bones of the forearm. Osteochondritis may occur, however, in flat bones.

Levaditi, Hoffman and Bertarelli frequently found *Treponema pallidum* at or after the fifth month in osteochondrotic tissue.

Periostitis ossificans is also found occasionally in congenital lues.

Congenital rickets is thought by some to be only a congenital predisposition to rickets, while another school thinks, and has good evidence to prove, the presence of rickets in the fetus in utero, caused by the same factors as produce rickets later on.

In rickets there is accelerated multiplication of cartilage cells and a retardation in the deposition of true bone resulting from a failure in deposition of the calcium salts. It is evident that in the causation of rickets or, for the growth of normal bone, many factors are involved. In the first place, the presence of vitamin D is essential. This may, however, be replaced to a certain extent by exposure to sun's rays or to ultraviolet light. Then it is necessary that calcium salts shall be present in proper proportions. Deficiency of calcium and phosphates in diet may hinder the formation of bone.

Infarcts of the placenta may modify the development of the entire fetus, thus modifying the bone development at the same time.

Oligohydramnios might modify the development of bone, by producing intrauterine amputations or pressure deformities.

Chondrodystrophia fetalis or micromelia is shortness of limbs. Changes in the skeleton are derived essentially from retardation of the epiphyseal growth of the bone, with normal periosteal growth. The structure of the bone produced with the periosteum is very dense, and results in the coarse sclerotic quality of the bone. The formation of synostosis takes place in the synchondroses and syndesmoses. The junctions of the epiphyses close prematurely, and the further growth in length is impeded by the coalescence of the latter. The cause of the disturbance is thought to be a disturbance in the internal secretory equilibrium, with evidence that in these fetuses there are generally insignificant, but frequent changes in the thyroid, liver and genital development. However a living infant born at the Long Island College Hospital in the month of April, 1929, was typical of micromelia, especially marked bilaterally in the humeri and femora, yet apparently there were no gross thyroid, liver or genital changes observable. There was a slight degree of hydrocephalus. The mother was normal in every respect physically.

In osteogenesis imperfecta, the most characteristic symptom lies in the abnormal brittleness of the bones, and after birth such children exhibit multiple incomplete fractures, due to the thinness of the cortical bone layers. The extremities may be bent in a circle, due to fractures. Otherwise the condition of the child presents nothing abnormal. The cause of this condition is not known.

Roentgenograms may be used *per se* to determine the bone development, and the roentgen ray bears an important part in the medico-legal aspect of obstetrics. The stained specimens present detail and relationships in three dimensions, so that when used as controls, and checked over by roentgen rays, one can more fully read and comprehend the roentgen ray picture.

The stage of ossification of the skeleton of a fetus, as observed in roentgenograms, is used practically to determine the age

of the fetus. This method however is far from accurate, and this can be easily shown by comparing the two pictures of the three-month-old fetuses. One has fairly good bony development, and the other, due to diseased condition, has marked retardation in calcium deposition. The centers of ossification in the diseased specimen are almost equal to that of the normal specimen, and therefore, using the number of centers of ossification as an index to age might be more accurate. These points are much more clearly visualized on study of the cleared specimens up to four months of age, because up to this age roentgen rays are very indistinct. Using the cleared specimens as controls, the study of these centers of ossification is greatly facilitated.

Mall, through a special technic proved in specimens under 100 days old that centers of ossification are present at least one week before they are demonstrable by roentgenograms. Anatomically these observations are definitely proved by the cleared preparations.

In the very early period of the second month the stage of ossification of the clavicle and the mandible is of chief importance.

The results used for comparison are from the combined findings of several years of laboratory work, the chief details of the *modus operandi* having been stated at the beginning of this paper, supplemented by a large number of photographs and roentgenograms. The photographs were taken in a dark room by means of transmitted light. The roentgenograms required careful study so that detail and contrast could well be brought out, the best result being had with high milliamperage and increased distance of the object from the target. The smallest specimen, three months of age, was best at 40 ma. distance of 36 in. and time $\frac{3}{4}$ sec. The full term fetus showed best at 40 ma. and 36 in. distance and the time at exposure was 2 sec. This technic gives the best black and white contrast.

SUMMARY

There are several possibilities for use of the data given here.

1. The observer can have an open view of the study of the progress of the development of bone in the fetus.

2. The relationship of the bones to each other and to the rest of the body can be studied in true anatomical position.

3. The results can be used in obstetrics especially in roentgen ray work, the stained specimens acting as controls as far as detail and number of calcification centers are concerned, as an aid in judging the size. The truest picture of fetal changes is obtained by a detailed study of the stained specimen, especially in the earlier months. Roentgen pictures of the fetus taken at the same period show a marked lack of detail when compared with the stained specimen. The possibilities in this are great, and a decided increase in efficiency in obstetrical diagnosis in the early months of pregnancy may be obtained by careful comparisons of the roentgen ray plates with the stained specimens, for the purpose of so perfecting the roentgen ray technic that it may bring out details which are now only observable in the stained specimens.

In the special work, roentgen rays of specimens of all ages were superimposed over the roentgen rays of the normal female pelvis, and the results are clean cut. One may argue that with the fetus in utero the conditions are different and there is greater body resistance with greater chance of distortion and absorption of the roentgen rays. There is some truth to this argument, but the results had from ordinary roentgen rays, and the roentgen rays of the fetuses when studied out carefully with regard to the various factors of distance, time and milliamperage, compared with the stained preparations, show that the earlier roentgen ray diagnosis can be made more certain.

4. Earlier determination of bone pathologies of the fetus in utero, especially of luetic osteochondritis when lues is

suspected, are made possible even though clinical data are missing.

My especial gratitude is due Dr. Adam M. Miller, Head of the Department of Anatomy at the Long Island College Hospital, who made available to me the

facilities for carrying on this work and also to Dr. Bell, Head of the Department of Radiography, through whose courtesy and cooperation the photographs and roentgen ray studies appearing in this article were made possible.

EMBRYOLOGY, ANATOMY AND SURGERY OF THE PROSTATE GLAND

WITH REPORT OF OPERATIVE RESULTS*

OSWALD SWINNEY LOWSLEY, M.D., F.A.C.S.

NEW YORK

AMONG the various structures which make up the genitourinary tract the prostate gland has, until recent times, remained something of a mystery. By the earliest anatomists it was regarded as a urinary organ, and after its identification as a part of the generative system, its anatomy, histology and function were imperfectly understood, and its pathologic manifestations remained a vexatious problem to students of urology right up to our own time. Indeed even now many of the points that these students have from time to time brought forward for elucidation are still unsettled, and capable of stirring up a considerable amount of acrimonious partizanship when brought up for discussion, a sure proof that we have still a good deal to learn about this diminutive but highly important part of the male organism.

When I first entered upon the study of prostatic anatomy and physiology, a review of the existing literature revealed an amazing divergence of opinion, especially in the department of embryology, the particular rock upon which unanimity always seemed to be shipwrecked being the integral relationship of the "middle lobe" to the rest of the structures about the vesical neck.

EMBRYOLOGIC DEVELOPMENT

My investigations of prostatic embryology were carried out upon specimens varying in age from ten weeks to full term, and study was further visualized by the construction of a wax model of the human prostate gland as it appears at birth.

The study was begun with a fetus 5 cm. in length, estimated age ten weeks. At this

stage of development the bladder is a cylindrical tube made up of embryonal connective tissue, joined near its base by the two ureters. These two ducts pass through the wall of the cylindrical bladder, and the muscle fibers which form them extend so as to be superimposed upon the vesical wall, thus forming the trigonum vesicae. No tissue which in any way resembles muscle is to be detected, nor can one distinguish the area which will later on be occupied by the vesical sphincter, except that alternation in the size and shape of the lumen is evident. In a fetus of thirteen weeks' development, however, this muscular development has been initiated, for circular interlacing of the fibers has commenced, longitudinal strands of tissue which take on a deeper pink color than that assumed by most of the connective tissue of the vesical wall being in evidence. The bladder base has thickened until it is deeper than any other portion of the circumference, and the wall beneath the trigonal area with the overlying trigonum vesicae has a depth five times that of the anterior wall. It is now possible to trace the trigone's muscle fibers from between the two ureters down upon the remainder of the trigone, and it is noticeable that their texture is much finer than that of the fibers of the vesical wall proper. An abrupt narrowing in the circumference of the lumen indicates where the vesical sphincter will shortly emerge as an entity and at this period of development also, a few muscle fibers displaying the circular arrangement are in evidence.

By the time the sixteenth week of fetal development is attained there is a great advance in formation of bladder muscle, the difference between muscle fibers and

* Read before the Section of Genito-Urinary Surgery, New York Academy of Medicine, May 15, 1929.

connective tissue being sharply defined. The fibers forming the vesical trigone are in evidence from their place of emergence from the walls of the ureters, so that their course to the trigone area is easily traced, and in the specimen of this age which was examined, the mucosa was smooth and closely adherent to the trigone, though elsewhere it was arranged in folds. The constricted opening of the vesical neck was sharply outlined by encircling muscular fibers indicating the position of the vesical sphincter. In a specimen twenty weeks old there is a very great increase in the number and size of these fibers, so that the internal sphincter seems to be tightly closing the vesical orifice. All the muscular fibers are much more in evidence, the longitudinal ones running in among those upon the outside of the sphincter. Though folded every where else, the mucosa over the trigone is quite smooth at this stage.

In a specimen of twenty-two weeks' development the musculature of the bladder has undergone still greater augmentation, and the same is true of the interureteric bar. The relation between the size of the trigone and its underlying bladder wall to that of the remainder of the wall of this viscus has now changed, for this part of the wall has not enlarged as rapidly as other sections; the fibers forming the trigone show a closer binding together than those of the rest of the bladder, while the mucosa covers it smoothly; the sphincter, though large, is in very close relation to the rest of the vesical musculature. At the thirtieth week and at full term the muscles of the bladder wall will be found to have increased still further in size, for at birth the sphincter is very thick in its posterior quadrant, and shows its greatest dimension at the upper margin. At this time many of the muscle fibers, instead of circling the orifice, mingle with those showing a longitudinal arrangement which originate on the anterior surface of the bladder. The fibers visible at the outermost part of the sphincter are not now so numerous,

but those in evidence entirely encircle the opening.

It is not until the third month of fetal life that there is evidence of development of the prostate gland. At this time solid epithelial outgrowths make their appearance from five distinct parts of the prostatic urethra. These solid masses are made up of cells which stain very deeply, and very early these assume a circular arrangement forming a lumen and branches and thus producing the tubules which are the prostatic nucleus. From the five different points of origin there thus arise five groups of tubules, the first lying on the floor of the urethra between the vesical neck and the orifices of the ejaculatory ducts and prostatic utricle; the second and third on on either side the urethra in the prostatic furrow; the fourth just below the point where the ejaculatory ducts and utricle open into the urethra, upon the urethral floor; and the fifth in the prostatic urethra upon the ventral or anterior wall. By the development of these tubules and their enclosure in stroma; there eventually arise five lobes, namely the middle lobe, right and left lateral lobes, posterior and finally, anterior lobe. Widely separated in the early stages of embryologic development, the distance between the middle and two lateral lobes is greatly diminished in later fetal life. None of the specimens studied showed any actual intermingling of the tubules, but after birth the middle lobe and lateral lobes lay side by side, with no definite separating capsule between them. The posterior lobe, however, was entirely distinct, a dense layer of fibrous tissue separating it from the lateral lobes, and the anterior lobe was at a considerable distance from the two lateral lobes, separation being quite complete.

The youngest fetus examined showed no sign of muscular fibers about the prostatic tubules, but at the sixteenth week a slight differentiation in staining properties was noted and by the twenty-second week there was considerable development of the muscle layers, especially at a point

where certain of the tubules of the lateral lobe extended away from the base of the prostate. This muscle structure constantly increases in thickness as older specimens are examined, until at full term an extremely dense layered structure surrounds some of the tubules.

The Middle Lobe. As one among the specimens examined in the course of this study had no tubules developed in the usual location of the middle lobe, the investigation was extended to adult dissection and autopsy subjects in order to determine the relative number of individuals who possess this portion of the gland under consideration. In all, 103 specimens were examined, and among these there was but one, the fetus in question, in which there was undoubted absence of glandular tissue in the middle lobe region, though in 5, 3 of which were seen at Guy's Hospital Pathological Museum, London, it was not possible to determine whether or not glandular tissue was present.

The middle lobe in all the fetal specimens examined was seen to develop independently from the group of tubules lying on the floor of the urethra, at a point between the bladder and the orifices of the ejaculatory ducts. In the younger specimens this group was a long way from those which were the origin of the lateral lobes, but as older specimens were examined, the area intervening in which no glandular elements could be detected gradually decreased until, though the tubules and their branches did not lose their characteristic position, there was no longer any distinguishable fibrous capsule separating the middle from the lateral lobes. As the structures of the verumontanum develop, the ducts of the largest tubules, originally close to the middle line, are displaced so that they open high up on its sides, their original position being occupied by the ejaculatory duct openings and that of the prostatic utricle. The average number of tubules in the middle lobe, in this study, was found to be ten.

The Lateral Lobes. The number and

size of the tubules composing the lateral lobes were found to be greater than in any of the other lobes. The lateral lobe tubules originate on the lower part of the lateral walls from the right and left prostatic furrows, forming the major part of the prostate's base by backward and outward extension. Though there is always a certain degree of separation between these lobes, it is much greater in the early specimens, the nearer the full term of gestation is approached, the less definite this separation becomes, except at the point where the ducts communicate with the urethra, where the distinction always remains evident. The tubules always grow back toward the bladder, except in the apical region; here a few of the lateral lobe tubules send branches in a forward direction. In the one specimen where the middle lobe was absent, branches from the lateral lobes developed into the region which the middle lobe normally occupies. In a specimen from a new-born infant, the lateral lobes displayed two tubules which branched widely, so that they formed practically a glandular commissure by extending up into the region of the anterior commissure. Usually the lateral lobes show a considerable extent of stroma between their anterior protions, anterior lobe tubules being present in this stroma. A definite plane of connective tissue lies between their posterior branches and the posterior prostatic lobe, and mesially the ejaculatory duct, the urethra and the middle prostatic lobe intervene. The average number of tubules in the two lateral lobes was reckoned to be thirty-seven.

The *posterior lobe* was found present in every specimen examined, as an independent structure developing from tubules which are distant from those from which the other lobes develop, and divided from the other lobes by a definite capsule, only connected laterally with that enclosing the entire gland. The tubules of this lobe appear at the third month of fetal development together with those of the other glands, and are found on the urethral floor

below the openings of the ejaculatory ducts. They develop in a backward direction toward the bladder, thus advancing behind the ejaculatory ducts, and forming the major portion of the prostate's apex, the portion of the fully developed gland which can be palpated by rectum. The posterior lobe is separated, by a stroma of connective tissue containing no tubules, from the ejaculatory ducts and the posterior sections of the lateral lobes, although this stroma is not in evidence in the earlier months of fetal development. In this division of the prostate gland the tubules are relatively large and have numerous branches, but they are few in number, the average in six specimens being only eight. Their branches, like those of the tubules of the anterior lateral lobes, extend forward into the apical region.

The posterior lobe of the prostate is of especial interest to surgeons, for it has been established that it is the site of carcinoma, but that benign hypertrophy seldom takes place in it. We are indebted to the late John T. Geraghty and to Montague L. Boyd for studies in prostatic pathology which have supplied us with this information, and when we add to this the further knowledge gained by embryologic investigation, which shows that the tubules from which this lobe takes its origin are entirely independent of the other tubules forming the remaining prostatic lobes, it at once appears highly probable that the function of the posterior lobe may be distinct and different from that of the remainder of the gland. This view gains further confirmation when examination of the posterior lobe tubules in the fully developed adult, shows them to be much larger than others.

The *anterior or ventral lobe* enters upon its developmental stage at the same time as the other lobes, being formed of large tubules having numerous branches. The size of these tubules, however, does not remain relatively so large, for by the time development has advanced to the sixteenth week they are even somewhat smaller than the tubules of the other lobes, and

by the twenty-second week they have decreased both in number and size, and appear to have lost most of their branches. In fact the anterior lobe becomes increasingly insignificant as development advances, until when full term is reached only two small tubules are in evidence. The anterior lobe may, however, persist to the period of full adult development, for among the adult prostates which were examined in connection with this study, numbering 93, 2 specimens came under observation in which hypertrophied anterior lobes were present. The average number of anterior lobe tubules in the fetal material examined was thirteen for the first half of the interuterine period, and six for the second half of this period. Kuznitzky reported the finding of a persistent ventral lobe in 1 out of every 15 adult prostates which he examined.

Prostatic Duct Openings. One of the significant results of this investigation was that relating to the number of prostatic ducts which have openings upon the floor of the prostatic urethra. In the majority of textbook descriptions the number of these openings has usually been given as from twenty to thirty. I am convinced, however, that this estimate is far below the actual average. Summing up my findings in regard to this particular point, it turned out that no specimen examined showed less than fifty-three of these ducts opening into the prostatic urethra; 2 specimens showed as high as seventy-four, and the average for 6 specimens, in one of which there was no middle lobe, was sixty-three. And never, since I first published the results of my enumeration nearly fifteen years ago, have I seen any refutation of my figures, though many textbooks, even those which have undergone revision in the meanwhile, still continue to make the original estimate.

SURGERY

Great progress has been made in the surgery of the prostate gland in the past few years. A review of the steps marking

progress of surgery of the prostate gland is interesting. The problem of this particular field of surgery is complicated by the fact that all of the patients are men of advanced years.

The discovery of anesthesia and the application of the principles laid down by Lord Lister placed this branch within the limits of surgical aid along the usual lines. It was soon learned that the aged men, most of whom suffered from deficiency in renal power, tolerated ether poorly and various efforts were instituted to avoid the frightful mortality that resulted from this operation under ether.

It was early recognized that those patients, who were catheterized over long periods, if they survived, were in better condition for operation when it was finally performed. This knowledge led the progressive urological surgeon to institute some sort of drainage as a routine preliminary to operation. This drainage may take one of three forms:

- (1) Regular catheterization once or twice daily
- (2) Retained catheter per urethram, or
- (3) Suprapubic drainage under local anesthesia.

Personally I prefer the last method because the other two are irritative and annoying to the patients and we find that even under the most careful precautions the patient will be inflicted with either a primary cystitis or a secondary exacerbation of an already existing infection.

The Urological Department of the New York Hospital is provided with suction in every room so that the patients are kept dry and comfortable by attaching the suction to the inner of a double tube which has been in use for many years. The urine rises in the large outer tube until it reaches the lower end of the small inner tube, which is surrounded by a column of air, and the patients abdomen is kept dry by this means without sucking the bladder wall into the end of the tube.

The general observation of the improvement in the renal power of patients by

drainage was placed on a scientific basis by the development of accurate methods of measuring kidney efficiency. These methods have gradually improved, stimulated no doubt by the epoch-making work of Geraghty and Rountree on phenolsulphonephthalein in 1908. Various other tests are in use including cryoscopy, estimation of output of various substances, such as potassium iodide, sodium chloride and others. The color tests, phenolsulphonephthalein and indigo carmine, deservedly occupy the most important place among kidney efficiency tests in the order named. The Mosenthal concentration test is an important recent addition to this list.

Perfection of methods of estimating various retention products in the blood stream of persons suffering from inefficient kidneys is a most important addition to our investigation of the patient, preliminary to operation. By determining this retention, by estimating the excretion of urea in a twenty-four hour specimen and by doing a phenolsulphonephthalein test, one may get a true picture of the extent to which the kidneys are performing their function as eliminative organs.

The most important part of any operation upon the prostate gland is the preparation of the patient. This preparation consists of drainage by any effective method that is least annoying to the patient.

The patient having been properly prepared, as indicated by his laboratory tests and as shown by the observing eye of the operator, it is necessary to decide which type of operation one must use. It seems most unwise for the urological surgeon to close his mind to any type of operation. It can be clearly decided by the cystoscope or by digital examination at the preliminary suprapubic cystotomy whether the hypertrophic gland should be removed by the suprapubic route or through the perineum. Unless there is some specific reason for the gland to be removed subrapubically it would seem much more preferable to perform the perineal opera-

tion because while the latter requires more time and an intimate knowledge of the anatomy of the region, it is not nearly so great a shock to the patient. The reason for the shock accompanying the upper route is that there is always more or less pressure and traumatism to the complicated nervous plexuses over which one must work, thereby exerting an effect similar to a blow over the solar plexus, so familiar to everyone. The downhill drainage and the fact that the patient can be gotten out of bed in a chair after the third or fourth day are additional arguments in favor of the perineal operation of Young and its modifications and the excellent perineal operations of Voelker of Halle and Syms of New York.

Next to the preliminary drainage the choice of anesthesia assumes a much more important rôle than does the choice of operation routes. Ether is dangerous because it is extremely irritative to the kidneys, which even in the best of cases are already damaged. Chloroform is almost sure death, the patients succumbing in from six to ten days as a result of liver poisoning as shown by the experiments of George Whipple. Of the inhalation anesthesia, gas oxygen is the most serviceable, but there are very definite objections to it. Under all inhalation anesthetics the blood pressure is elevated very considerable so that the patient may be likened to an athlete at the height of his activities. This naturally gives rise to more bleeding and consequently to greater shock. Many attempts have been made to perform the operation under local or regional anesthesia. Of these methods two have survived. Spinal anesthesia as practiced by many urologists from time to time in this country and sacral anesthesia which has been lately modified by the addition of parasacral injections as well. The number of accidents under spinal anesthesia has been so great and so fatal that it has been largely given up by American surgeons. The results with sacral anesthesia have been so spectacular in a recent series of cases

that it seems worth while to discuss the method in some detail.

F. Cathelin³¹ and Durant (1902) used sacral anesthesia for the purpose of treating grave neuralgias, sexual neuroses, and incontinence of urine. The former first used plain water, salt solution and later added cocaine, novocaine, codeine or morphine. By this method Cathelin reported 49 per cent of the cases of incontinence of urine cured: 35 per cent materially benefited and 4 per cent failures. He failed in his attempts to completely anesthetize the sacral nerves in humans but was successful in dogs.

A. Lowen³² used 20 to 25 c.c. of 1.5 to 2 per cent novocaine and placed the patient in a sitting posture for some minutes after injection with the idea of retaining the solution in the lower end of the vertebral canal. O. Gros³³ recommended the addition of sodium bicarbonate which he states permits the solution to readily penetrate the nerve sheaths. Strauss prepares a solution by the addition of sodium sulphate which he maintains prevents the decomposition of adrenalin, which he also uses. Hertzler recommends the uses of quinine and urea using 60 to 90 c.c. of 0.6 per cent solution. B. Lewis and L. Bartles³⁴ reported 48 successful cystoscopies out of 68 attempted and D. R. Pickens³⁵ reported 81 out of 100 attempted.

Splendid work on this subject has been done by Thompson of Galveston who follows the method described by M. L. Harris.³⁶ Albert J. Scholl, Jr.³⁷ used sacral anesthesia successfully in 140 cystoscopies out of 150 in which it was used. He used the method recommended by Labat.

The patients upon whom this type of anesthesia was first used by us were all cases in extremely grave condition.

All cases have been entirely successful except 6. In one of the latter, a seminal vesiculectomy, it was necessary to give a few whiffs of ether during the last five minutes of the operation. In another, that of a man of eighty-six years of age upon whom a perineal prostatectomy

was performed, a little gas or ether should have been used for about the same length of time. A third case was only moderately uncomfortable.

Untoward Symptoms. Two cases have had short periods of excitement. One had spasmodic contractions of the legs lasting about one minute. Two others became flushed and somewhat confused temporarily. Most of the cases have an increase in pulse rate and slight increase in blood pressure which lasts throughout the operation.

The untoward symptoms in our cases appeared immediately after the injection was given into the sacral canal and caffeine is always held ready for use in case a collapse occurs.

E. Zweifel³⁸ reported a death from cardiac and respiratory paralysis due to the injection of 0.8 gm. of novocaine into the dural space. His needle had penetrated the dural sac. B. Kronig³⁹ reported a case in which the novocaine was injected into the sacral vein. This was followed by a partial respiratory paralysis.

Preoperative Preparation. When first seen the patient suffering from residual urine should have his bladder partly refilled with boric acid solution or sterile water whenever catheterized. The amount replaced can be reduced gradually if the patient shows no toxic signs from this procedure. This is called "decompression" and is of vast importance in the prevention of uremia from the complete emptying of an overdistended bladder.

Following the period of decompression it is the practice of the author to do a suprapubic cystostomy for drainage, using a suction apparatus which drains the bladder by means of the double suction tube devised by Kenyon of the New York Hospital and recently modified by Harrah.

The indwelling catheter method of drainage has many objections. The intrusion of a foreign body through the urethra prevents the proper drainage of the fluid from the prostatic tubules and causes additional congestion of the prostate gland.

There is sufficient absorption from the prostatic urethra to keep the patient a little below par at all times.

The suprapubic drainage under suction seems to be the ideal method of procedure as a preliminary to operations on the prostate.

It is an efficient method. The patient keeps dry, clean and odorless. Old men are very much like babies in that if they are dry, clean and comfortable they will thrive but if they are wet, odoriferous and uncomfortable, they, like babies, wilt and do not progress favorably.

By this efficient method of drainage the edema of the prostate is reduced, absorption does not occur and at the time of operation the hemorrhage is considerably reduced. By using a satisfactory binder the patient may sit up on his fourth postoperative day.

Vaccination of the patient by the organisms carried in his bladder occurs at the time of cystostomy. Thus we see that the shock of the prostatectomy is divided into two parts. Indeed the patient is usually more uncomfortable after the first operation than he is after the second.

The important thing about the length of time to be devoted to preliminary drainage is to have no set time for it. By a succession of blood chemical and phenolsulphonephthalein tests one determines when the patient has reached his maximum of renal efficiency. If at the same time the patient feels well and is anxious to proceed, the prostatectomy is then undertaken. One must continually bear in mind that we are dealing with human beings and regardless of the excellence of laboratory tests, if the patient is weak, decrepit or even has a headache it is wise to wait until he, like a well-trained athlete, is "raring to go." Also like athletes, patients waiting around a hospital may go "stale." This is reflected in the patient's well-being as well as his laboratory tests. Such cases must be postponed until they have entirely resumed a state of well-being. The shortest period

of drainage in our series has been eight days, the longest twenty-four months, while the average length of time is sixteen days.

Due to hemorrhage and infection the patient may have a badly depleted circulatory system. In such cases, transfusion, repeated if necessary, of moderate amounts of blood is particularly helpful.

Purgatives are administered the day before the operation sufficiently early so that the patient may have a good night's sleep. Sodium bicarbonate is administered in small doses for a period of two days before operation. Fluids are taken up to, during and immediately after operation so there is no dehydration of the patient.

Operation. The most important feature of an operation on the prostate gland is proper preliminary drainage. Next in importance is the anesthesia used and of least importance is the route by which one removes the gland.

General anesthesia should be avoided because it elevates blood pressure and hence there is more hemorrhage during operation. As soon as the patient recovers consciousness he has the pain caused by a fresh incision. These two factors, pain and increased hemorrhage, explain why eight times as many patients went into shock or bordered on it when we were using general anesthesia, than we see now.

The administration of sacral and parasacral anesthesia has been thoroughly described by us elsewhere. The method is easily and almost painlessly applied and has been used on many cases with almost no accidents. Its advantages are many. It is possible to get perfect anesthesia for perineal prostatectomy in 95 per cent of the cases, the remaining 5 per cent require slight reinforcement in some manner. Often the smelling of a little essence of orange or a few drops of ether sprinkled on a piece of gauze are sufficient to accomplish the desired results.

As far as one is able to estimate there is about $\frac{1}{10}$ the amount of bleeding as

compared to the same operation under general anesthesia. The anesthesia persists for a period of six to eight hours after injection to a certain degree and for two hours for purpose of operation. This fact prevents postoperative pain to a large degree. Thus the main elements which go to make surgical shock are eliminated. Water is imbibed throughout, thus preventing dehydration.

The operation which we prefer is a modification of Young's perineal operation. The splendid tractor devised by Crowell is first passed into the bladder through the urethra. Its blades are then opened. After making a semilunar incision through the skin the two spaces on each side of the central structures are opened by sharp and blunt dissection. The central tendon of the perineal muscles are then incised *behind* the point where the lateral perineal muscles join it. This allows the central structures to be pulled upward with the bulb and lateral perineal muscles. A Kocher clamp is fixed to the posterior part of the central tendon and held in the left hand for the purpose of traction. The index finger of the left hand is inserted into the rectum and the hand covered with a towel. The dissection is carried deeper and the important reflection of the levator ani called the rectourethralis, attaching the rectum to the urethra at the apex of the prostate, is then incised. The levator ani is then dissected from the posterior surface of the prostate which is recognized by the glistening fascia of Denonvillier which covers its posterior surface. It is thus noted that not only has the posterior urethra not been opened but often it is not even seen, which is an extremely important point in the prevention of incontinence. The left index finger is now removed from the rectum and the glove changed, a posterior retractor being placed in position.

The prostate is now opened by making an inverted v slit in its posterior surface, the apex of the incision reaching the exact apex of the prostate and being carried

down to the urethra itself. When this flap is drawn back the verumontanum is seen and a transverse incision is made in front of it. This is deepened by blunt dissection which separates the middle lobe from the posterior lobe with its dividing fibrous leaflet which carries the ejaculatory ducts through the prostate. This procedure leaves the ejaculatory ducts uninjured and still retaining their normal orifices. These facts account for the low incidence of epididymitis following our procedure.

The enucleation of the gland is now continued by separating the hypertrophied portion presenting from the capsule. The index finger is introduced into the prostatic urethra and the so-called anterior commissure split, being careful not to injure the internal sphincter any more than absolutely necessary. If the internal sphincter is split at the top there is grave danger of tearing into the plexus of Santorini with resulting hemorrhage.

The Lowsley clamp is now used to grasp the hypertrophied structure and the enucleation completed.

The vesical orifice is grasped with an Allis clamp, the Crowell tractor closed and removed and the finger of the operator introduced into the vesical orifice to identify and remove any remaining tags of tissue or a subcervical gland enlargement. Pieces of prostatic tissue as big as a lime are removed with the author's clamp through the vesical orifice without difficulty. Particular attention is paid to the thorough removal of small nodules of prostatic tissue and to tags of fibrous material as well. These half-destroyed tissues will remain as a future menace to the free passage of urine or become necrotic and offer a fertile field for the infection of the entire prostatic cavity.

A Pezer tube, size 26 F., is introduced into the bladder through the urethra and fixed in position by means of adhesive. The vesical orifice and prostatic cavity are now thoroughly packed with vaseline gauze, enough being used so that the bleeding is entirely stopped on the table. The

floor of the pelvis is closed by drawing the two sides of the levator ani muscle together with a catgut suture. The skin is closed with silkworm gut.

Postoperative Course. We have had only one death attributable to the anesthesia. In the first series there were 2 cases that could not have been operated upon except by means of sacral anesthesia as they were in no condition to withstand inhalation anesthesia of any sort. In the last series of 19 patients there is one such case. We have felt for sometime that blood pressure observations were much more important in the postoperative tests than any other feature of immediate recovery. It has been a surprise and delight to observe this series of cases. In none of the second series has the blood pressure dropped below 100 mm. Hg. and all of them have shown a tendency to rise at the danger period, about six hours after the operation. We have not found it necessary in any of these cases thus far to give stimulation to the circulatory system either by means of drugs, intravenous infusion of gum-glucose or any other substance.

The general appearance of the patients on the day following operation by this method is suprisingly good and it would seem that the shock to the entire body mechanism is very considerably reduced by avoiding inhalation anesthesia. There have been no late developments such as headache, paralysis or other alarming effects. Thus far our patients seem to improve from the zero postoperative hours (six to ten hours after operation) without interruption.

Postoperatively the prostatectomy patient must be handled and watched over as carefully as any baby. The patient operated upon under sacral anesthesia may take fluids without becoming nauseated, not only immediately after operation, but during the operation as well.

After the operation is over he should be allowed to rest quietly in bed which he will do in almost 100 per cent of the cases, because he remains somewhat under

PROSTATIC OPERATIONS UNDER REGIONAL ANESTHESIA UP TO JANUARY 1, 1928

James Buchanan Brady Foundation for Urology

| Diagnosis | No. of Cases | Average Age | Operation | Type of Anesthesia | Postoperative | | | | Other Complications | Average Length of Postoperative Stay in Hospital | Results | | | Mortality (Per Cent) |
|--|--------------|-------------|--------------------------|--|---------------|--------|------|-------|------------------------------------|--|---------|----------|------|----------------------|

the influence of the narcotics and anesthesia for hours. He should only be disturbed to administer fluids and to take the blood pressure, which is the most important single test to make in such cases.

If the blood pressure drops unduly and does not rise (premonitory symptoms of shock) gum-glucose solution may be administered after the method described by us in 1921. Transfusion of properly tested blood may be administered in extreme cases. In case the bleeding has stopped, the packing is removed from the prostatic capsule in twenty-four hours, the tube is removed from the bladder on the third day and the patient permitted to sit up in a chair on the fourth day. Man is unquestionably an upright animal and apparently all bodily organs functionate better with the patient sitting in a chair than when he remains in bed. The patient receives a remarkable psychological boost when his feet touch the floor and one cannot help but be impressed by the fact that improvement is marked after he is allowed out of bed.

Upon revealing the results of operations upon the prostate one is forcibly impressed by the fact that age is no contraindication to operation whatever. In our series of cases there were 26 men over eighty years of age, of whom all except one lived for varying, considerable lengths of time after prostatectomy, and died of some other cause in no way connected with the operation.

Almost every case that recovers from a perineal prostatectomy is able to return to his customary duties. Provided both sphincters are not lacerated beyond repair there is never a resulting incontinence; apparently either sphincter may be totally obliterated, provided the other remains intact, without incontinence. Persistent fistula never results if the perineum is reconstructed by one stitch drawing the two parts of the levator ani together. Frequently patients whose prostates have been removed are able to enjoy sexual intercourse. Occasionally the ejaculated mass goes back into the bladder instead of being projected from the urethra.

The bladder, usually infected before operation, almost always afterwards will clear up under appropriate treatment provided the operation has been successful, and there is no residual urine.

Conclusion. In conclusion it is appropriate to state that the most important thing about an operation for the removal of an enlarged prostate is the preoperative preparation which is summed up in the one word "drainage." Next in importance is the choice of anesthetic. This should not be an inhalation anesthesia if it is possible to avoid it.

CARCINOMA OF THE PROSTATE

It will be seen by referring to the accompanying chart that there were 33 cases of carcinomatous prostate operated upon with a mortality rate of 10 per cent.

It is our practice to remove carcinomatous prostates which cause residual urine because even the most enthusiastic supporters of radium treatment admit that the application of radium has no beneficial effect on the relief of obstruction. Therefore we remove the prostate by the methods here described and as soon as the patient recovers from the immediate effects of the operation radium is administered to the prostatic bed in the form of emanation seeds or the element itself is applied. In our experience it is noted that there is little liability of the growth returning at the site of the prostate. The patients usually live from two and one-half to three and one-half years, ultimately dying of metastasis.

This method of treating carcinoma is well worth while as the patient does not die of uremia and does not undergo the distressful urinary symptoms which he otherwise would surely have.

PROSTATIC ABSCESES

Our series shows 40 cases of prostatic abscess operated upon by the perineal route under regional anesthesia. In a study made some years ago when the author had the honor of serving on Dr. Keyes' staff

at Bellevue, parallel series of cases were operated upon by the perineal and suprapubic route. It was found that the average stay in the hospital after transvesical prostatic drainage for abscess was 31 days, while by the perineal route the average postoperative stay was 16.9 days.

The average of our cases was 29.17 years. There were 2 cases of epididymitis and one case of septicemia following operation. The latter case recovered after repeated blood transfusions. The average postoperative stay was 10.83 days. None of these cases died.

TUBERCULOSIS OF THE PROSTATE

Two cases of tuberculosis of the prostate were operated upon. A mistake in diagnosis was made in each case. One aged fifty-three showed prostatic shadows in the x-ray and the palpating finger detected a grating. The provisional diagnosis was prostatic calculi. Operation revealed what was considered a calcified tuberculous abscess of the prostate. This diagnosis was confirmed by the pathologist.

The other patient, aged sixty-nine years, had a prostate three times the usual size which caused a residual of 5 vi. It was removed in the customary manner. The pathological report showed it to be "hyperthrophia fibroadenomatosa prostates and caseous tuberculosis of the prostate gland."

These patients made uneventful recoveries.

CASE OF ENLARGEMENT OF THE PROSTATE GLAND SHOWING SOME OF THE CHARACTERISTICS OF HODGKIN'S DISEASE

Our case at the James Buchanan Brady Foundation for Urology of the New York Hospital presented a definite lymphocytosis, a moderate anemia of the chlorotic type, an enlargement of the chain of inguinal lymph nodes on each side, a loss of weight and strength and an impaired appetite and the general appearance of a tuberculous individual, all associated with marked enlargement of the prostate, acute

retention and urinary symptoms of only three months' duration.

The case presented the following history:

A single man, aged thirty-two years, was admitted to the Medical Division of Dr. W. R. Williams on December 7, 1926 and transferred to the Urological Division, December 11, 1926. He stated that his father died at the age of fifty-nine, from cancer of the liver. He was ill fifteen months. His mother died at the age of twenty-eight, from pulmonary tuberculosis. She was ill one and one-half years. He has one brother and two sisters, all living and well. He denies lues and gonorrhea by name and symptoms. He had mumps ten years ago. Pneumonia fourteen years ago. Until four years ago he was a chronic drinker. Since that time he has never touched liquor.

About three months before admission to the hospital he developed a moderate frequency of urination by day and by night. As time progressed this condition grew worse and was associated with painful and difficult urination. He noticed no pus or blood in his urine. His sexual powers were undisturbed. Three days before admission to the hospital he was unable to void except with utmost pain and difficulty. He finally developed acute retention and was brought to the hospital in an ambulance. His bladder was decompressed gradually by means of a retention catheter. He was fairly well nourished and seemed in moderately good health, although he stated that he had lost 20 pounds during the past six months and during the past three months he had grown progressively weaker, but had not been confined to his bed. He had no cough. His bowels moved regularly. His appetite was impaired. He did not suffer from insomnia but grew dyspneic on slight exertion.

His general physical examination was negative except for moderate bilateral enlargement of the inguinal lymph nodes and a small fibroma on the inner aspect of the left thigh. His liver and spleen were not palpable. Chest negative. The lower poles of both kidneys could be felt as well as the distended bladder. Rectal examination revealed slight hemorrhoids. The sphincter tone was good, the prostate was about twice the usual size, it was hard on the right side but did not have the boardlike rigidity of carcinoma. The left side of the prostate seemed normal in consistency

and not fixed in position by adhesions. The left seminal vesicle was palpable but not enlarged. The right was barely palpable. The impression gained at that time was that the patient was suffering from enlargement of the prostate with retention of urine.

Cystoscopy under caudal anesthesia revealed a diffusely reddened vesical fundus. Ureteral orifices were not distinctly seen. The vesical orifice was most interesting in that it showed a tremendous intrusion of the subcervical group on its floor.

Blood urea nitrogen 17 mg. per 100 c.c. Blood sugar 0.112 per cent. Carbon-dioxide combining power of the blood plasma 56 volumes per cent. The phenolsulphonphthalein test showed a secretion of 60 per cent in two hours at one examination and 75 per cent at another.

Blood Wassermann reaction was negative with both antigens on two occasions. Cultures from bladder urine showed *B. coli communis* and *Staphylococcus albus*.

Urine examination: Reaction acid, Specific gravity 1018. Trace of albumin, no sugar, no acetone.

Microscopic examination showed many red blood cells, few white blood cells, occasional epithelial cells, no crystals, no casts.

Complete blood was made on two occasions as follows:

| | December 8, 1926 | January 9, 1927 |
|---|---------------------|--------------------|
| Red cells..... | 5,112,000 | 4,815,000 |
| Hemoglobin, per cent..... | 93 | 88 |
| Color index..... | 0.91 | 0.92 |
| White cells..... | 8,600 | 7,400 |
| Polynuclear neutrophiles, per cent..... | 54 | 46 |
| Lymphocytes, per cent..... | 38 | 44 |
| Large non-nuclear, per cent.. (Transitional) | 6 | 7 |
| Eosinophiles, per cent..... | 2 | 3 |

Blood pressure on entrance: 114 systolic, 62 diastolic.

X-rays of the genitourinary tract revealed both kidney shadows large in size and low in position. There was no shadow indicative of stone in the urinary tract.

The patient was subjected to a suprapubic cystoscopy under local anesthesia. Examination of the interior of the bladder revealed a mass extending from the floor of the bladder neck about the size of a walnut which was rather firm in consistency. A specimen was taken from this tumor-like projection and sent to the laboratory for examination. The bladder

was drained by suprapubic suction for a period of fourteen days, after which time the prostate was removed suprapubically under sacral and parasacral anesthesia. It was interesting to note that this growth had greatly increased in size since the first operation. The site whence the original specimen had been removed had grown out in a very irregular manner so that it represented a cauliflower. Malignancy was suspected. The prostate was removed completely except for one point on the left lateral aspect where it was densely adherent and apparently infiltrated into the capsule of the prostate. The patient made an uneventful recovery and was discharged from the hospital fourteen days after prostatectomy with good urinary control and wound completely healed.

The prostate was examined by Doctors Elser and Semsroth of the New York Hospital. The report is as follows:

The specimen consists of several irregular shaped pieces of tough tissue measuring from 1 to about 4 cm. in diameter. The outer surface appears yellowish white, somewhat translucent, opaque yellowish strands are seen running through a whitish matrix. The gross picture is not that of a carcinoma nor does it show evidence of a normal prostatic tissue.

The accompanying microscopic slide shows the picture of a chronic inflammatory process. The granulomatous new-formed tissue is rich in plasma cells and contains mononuclear giant cells of the Sternberg type.

The condition is inflammatory (a granuloma). Plasma cells and Sternberg giant cells point to Hodgkin's disease. The latter malignant lymphogranulomatosis starts in lymphoid structures and as a rule spreads to other lymphoid structures, leading to a general lymph node enlargement, always fatal. The localization, however, of the process at the neck of the bladder is most unusual in Hodgkin's disease.

An inguinal lymph node was removed and examined. Microscopic sections showed simple chronic lymphadenitis with no evidence of a granulomatous process like that seen in Hodgkin's lymphogranulomatosis.

The small tumor on the inner aspect of the left thigh showed on microscopic sections the picture of a fibroma durum covered by stratified squamous epithelium.

Summary of Findings. It is unusual to find complete retention of urine in a man

aged thirty-two years due to a solid tumefaction of the prostate gland.

The gradual onset of the symptoms exhibited by the patient is similar to those described by most of adenomatous enlargements of the prostate in old men. The usual frequent and painful urination culminated in complete retention of urine rather more rapidly than most cases of adenoma.

There was a rapid increase in the size of the intrusion in the two weeks' interval between the suprapubic cystosomy, at which time a piece of tissue was removed from the tumor for diagnosis, and the actual removal of the mass with the prostate. The spot whence the specimen was removed showed a cauliflower overgrowth such as one sees in almost any malignant growth under similar conditions.

Upon removal it was noticed that it enucleated quite freely except at one point on the left lateral aspect where it was densely adherent and had apparently infiltrated into the capsule of the prostate. The impression of the author at the time of operation was that the case was one of malignancy of the prostate.

The specimens removed when examined microscopically showed granulomatous new-formed tissue rich in plasma cells containing mononuclear giant cells of the Sternberg type.

The examination of the enlarged inguinal lymph nodes showed simple chronic lymphadenitis with no evidence of a granulomatous process like that seen in Hodgkin's lymphogranulomatosis.

CONCLUSIONS

It is concluded from observations of a large series of cases (373) that:

1. The most important item in the care of a case suffering from prostatic disease is a suitable drainage until the patient reaches his maximum of renal efficiency.

2. The author believes that the best kind of preliminary drainage is by means of suprapubic double tube suction, because such a procedure diminishes the

edema of the prostate and thus is a factor in reducing bleeding.

3. Sacral or parasacral is the most suitable type of anesthesia for prostatectomy. Its advantages are:

a. It is efficient.

b. It allows the patient to take fluids up to, during and immediately after operation.

c. The bleeding is very much less than it is with any kind of general anesthesia.

d. Anesthesia persists for several hours after operation making the administration of morphine with its attendant bowel stasis unnecessary in many instances.

4. Perineal prostatectomy is preferred because there does not seem to be so much shock as noted in the suprapubic operation. The postoperative drainage is accomplished by means of an urethral catheter which allows both the perineal and suprapubic wounds to close.

5. The average postoperative stay in the hospital has been reduced to 22.76 days.

6. Almost 10 per cent of the prostates operated upon were carcinomatous.

7. The mortality for the adenomatous cases was 5.7 per cent while there were 3 deaths out of 33 cases of carcinoma.

DISCUSSION

DR. JOHN MORRISSEY: Dr. Lowsley's enthusiastic and very interesting presentation of the principles which he has advocated for the past six year is very impressive but the fact that it is not entirely convincing and fully accepted is borne out by the very limited number of perineal prostatectomies which are being done in the hospitals of New York City. Some three years ago I attempted to make a tabulation in this regard and less than 30 cases were discovered in a total of 14 hospitals during the preceding twelve months. It would seem, therefore, that his principles, those of Dr. Young and other forceful advocates of the perineal route, do not fully obtain and for that reason, therefore, my own experience in this regard may not be altogether uninteresting.

In the past six and one-half years I have operated on some 275 cases of enlarged prostates and some 200 of these have been perineal operations. I must say that the greatest objection to the perineal route is the dribbling, lack of control incontinence that follows the operation. Dr. Young and others consistently deny that incontinence or any interference with control is a complication of a perineal procedure and yet you can meet any number of urologists who have seen numerous cases of disturbed control following perineal prostatectomy. The very fact that numerous modifications of the original Young operation have been devised to meet this complication would seem sufficient evidence that we have a definite problem to deal with. As a matter of fact, I have devised an operation myself which attempts to preserve the external sphincter, thereby overcoming this difficulty.

My feeling regarding dribbling is that it concerns solely the mechanics of the bladder in that in enlargement of the prostate you have a dilatation of the internal sphincter. This is generally functionless, and in the perineal operation it is practically impossible to avoid damaging the external sphincter. Often times this damage is not done until the prostate is pulled out from its bed when some fibers of the sphincter are torn. The tear may be only microscopic and yet it is sufficient to interfere with adequate control, particularly in the presence of a useless internal sphincter. After the wound is healed, even though the sphincter be torn, there are scars formed which provide a certain

amount of tension and assistance in enabling the patient to retain his urine. As this scar is gradually absorbed, however, the sphincter relaxes and in two years it may be fully determined whether or not the patient has or has not control which is satisfactory to him.

The urologists at Mayo Clinic point with certainty to numerous cases where this dribbling has not been observed until after the two-year period. It is my practice to thoroughly drain the prostatic bed and space inside the levators not only with a gauze drain but with rubber tubes and this is kept up for some ten days following the removal of the packing. This prevents a scar formation and you are able early in the convalescence to train the patient in developing control in the event that it is lacking at first. In my operation the prostate is removed around the urethra and in the capsule incisions they are carried to either side of the center rather than into the urethra themselves. There are numerous other outstanding features of perineal prostatectomy which are unparalleled in the consideration of the advisability of methods. First, as regards bleeding. It is a complication never met with. I have operated on some 125 cases where it has not been required to tie a single vessel. I avoid cutting the levator muscles, lifting them from the prostatic capsule, and in placing a deep suture through these muscles to close the wound you practically control the entire amount of bleeding met with. A further point might be made with regard to the safety of this method in patients over seventy-five years of age. I recently operated on a man eighty-nine years of age. As a matter of fact, he left the hospital today, exactly two weeks after his prostate had been removed.

As regards mortality. I do not feel there is a great degree of this. I simply insist that I feel much more certain as to the outcome in the perineal cases. You must take my word as to the ease of dressings and postoperative care following perineal prostatectomy compared with suprapubic prostatectomy. Here the judgment of one who has done an equal number of both must be accepted. It is interesting to note also the relative seriousness of complications. For example, a epididymitis after a perineal prostatectomy is generally much less severe than one following suprapubic prostatectomy. Let me bespeak a more earnest consideration of some of the advantages that this perineal prostatectomy offers and

I am sure if the procedure is utilized more frequently you will be amazed at the satisfactory results which will be obtained.

DR. HOWARD JECK: I happen to belong to the majority who favor the suprapubic method, but I agree with Dr. Lowsley in two of the points that he brought out namely, the advantages to be derived from decompression in those cases with a large amount of residual urine and the suprapubic method of preliminary drainage. I do not think the suprapubic route can be improved upon as far as preliminary drainage is concerned.

As for the control of hemorrhage, in my experience I cannot recall a case where the hemorrhage has not been satisfactorily controlled by the Pilcher bag. I have seen operators tie off bleeding vessels as Dr. Lowsley has described and think it is a beautiful procedure, yet I cannot but feel that, from my experience, it is quite unnecessary. In most instances the hemorrhage is not alarming and where it appears so it is satisfactorily controlled by the Pilcher bag.

I should like to ask a couple of questions. In the first place, has Dr. Lowsley encountered many cases of hypertrophy of the trigone with a bas fond behind the interureteric ridge, and if so, how does he handle the situation? Secondly, how many cases of incontinence has he seen after the perineal operation?

DR. MEREDITH CAMPBELL: I would like to ask a question about the method of decompression employed, that is the emptying of the bladder and partial refilling. I would like to know if these patients have shown any evidence of renal shock following this procedure. At Bellevue Hospital some ten years ago we made observations in a series of 25 cases admitted in acute retention because of prostatic hypertrophy. In these cases the bladder was emptied ounce by ounce, the bladder pressure being taken with the withdrawal of each ounce. I found that in all cases when 4 ounces had been withdrawn the bladder pressure was reduced 50 per cent. In some instances with the withdrawal of but 2 ounces the bladder pressure was reduced one-half. We felt that this represented the major portion of the cause of the renal shock associated with rapid decompression or evacuation. I wish to know if withdrawing all the urine and refilling with one-half the original amount is succeeded by any evidence of renal failure clinically.

DR. LOWSLEY, *closing*: Dr. Morrissey spoke

about the scar tissue surrounding the healed operation. That is very important. I did not say much about the postoperative treatment, but I think that every patient operated on should have a regular course of dilatation following it. We have here a circular wound, and all circular scar tissue will contract. I have seen a case who had not been dilated, who, in one year's time after his operation had a contraction to a pin point size of his vesical orifice, because he did not follow the advice which must have been given him to have himself dilated after operation. One year later he was passing practically all his urine through his suprapubic fistula, which had never healed. He was cured by an external urethrotomy and dilatation of the vesical orifice, because we could not enter the urethra:

Dr. Jeck asked about the formation of a bar (hypertrophied trigone). I have seen two or three cases of that sort, and practiced the procedure laid down by Hinman. I had one case recover with very excellent results. I excised the interureteric ridge and also cut Bell's muscle at the edge of the trigonum vesicae.

Incontinence: While practicing the old procedure that Young devised and which lasted for fifteen years without any modification (then six or seven modifications were made in two years) we used to have 10 per cent of cases with incontinence for long periods of time. We found that it was due to the injury of both sphincters; that is why we make such a point of not interfering with the structures around the external sphincter; we try to leave it undamaged. Since adopting this method we have had only one case of persistent incontinence which has caused the man all sorts of trouble. That is the only case I know of. We have had several patients who have had some relaxation, would lose a drop or two when they cough or sneeze . . . but the average case will have control in two weeks to two months.

Replying to Dr. Campbell's remarks about decompression: I do not think we have had a single patient develop uremia due to our method of decompression. The method used by Hamer, to put a reservoir of fluid at a certain height above the bladder and then lower it a little each day, is a very good method too; but as far as I know we have not put any one into uremia by this very simple device of putting back half of the amount of fluid and allowing the bladder to fill up.

POSTOPERATIVE PHYSIOLOGICAL STUDIES IN A CASE OF TRAUMATIC RUPTURE OF THE LIVER

WITH RECOVERY*

R. B. McKNIGHT, M.D., F.A.C.S.

CHARLOTTE, N. C.

THE liver is probably the most frequently injured viscus in the abdomen in abdominal injuries. Owing to its friable nature, size and anatomical position, concussion may cause a lesion of varying degrees of severity, slight and inconsequential or extremely grave. Sudden blows over the abdominal wall, particularly if they involve much surface, are prone to cause injury to this organ.⁷ It has a distinct tendency to split or crack in a more or less stellate manner, with massive hemorrhage and escape of bile.⁸ When Glisson's capsule is badly lacerated, the amount of hemorrhage is necessarily greater than when the trauma is limited chiefly to the liver parenchyma.⁴ Frequently other abdominal or thoracic organs or the diaphragm are injured also, thus producing more or less serious complications which may mask symptoms referable to an injured liver.

The causes of traumatic rupture are, of course, varied; gunshot wounds, stabs with sharp instruments and crushing injuries with or without a break in the skin. Stabs and gunshot wounds usually recover following immediate operation, provided there is not too much destruction of tissue. Rupture due to sharp concussion causes a much higher mortality. Ashhurst, quoting Boljarski, places the mortality after operation at 75 to 80 per cent.¹

The symptoms of subcutaneous traumatic rupture of the liver are well outlined by Graham, who reported 11 cases, one his own.⁶ There are several points I wish to lay some stress upon, however. (1) Intermittent severe pain radiating in various directions, depending on the site of the rupture. If the convex portion of the right lobe is injured, pain is referred

to the right scapular region as in cholecytic disease; if the concave portion is involved the pain is referred to the waist line anteriorly. Steiger¹¹ states: "A symptom usually present is pain radiating into the right shoulder as is commonly noticed in gall-bladder disease. This is real assistance in diagnosis of hepatic injury."

(2) Shock is usually present, although various observers have reported it at times almost absent. (3) Many have noticed a slow pulse. Erderly⁵ operated on a fatal case of liver rupture in a boy thirteen years of age with a perfectly healthy heart, who had a pulse rate of 60 in spite of severe intra-abdominal hemorrhage. He concluded that bradycardia cannot be considered evidence against intra-abdominal hemorrhage when other symptoms speak for it. Indeed, some surgeons have considered a slow pulse as indicative of liver injury. Orth⁹ reported a case in a twenty-seven year old man who had a pulse rate of 54 two hours after the accident. He stressed the fact that marked tension of the abdominal wall and bradycardia were the foremost symptoms in the pathological picture. Experimentally he was able to produce bradycardia in dogs after hepatic injury, but only when there was a profuse discharge of blood and bile into the free peritoneal cavity. (4) Board-like hardness and exquisite tenderness occur over the involved area as a rule. (5) There is a sharp rise in the leucocyte count, whereas the erythrocyte count and hemoglobin may be slower in dropping. (6) In severe injury jaundice seldom appears before the third or fourth day, and it may not appear at all.

Treatment consists in early operation, utilizing whatever methods are deemed

best on sound surgical judgment to control bleeding in the individual case. Transfusions are, of course, indicated, and probably

Clinic has found life incompatible with a minute amount of liver tissue left free in the abdomen.

FIG. 1. Hemoglobin, red cells and white cells.

the earlier begun the better. White¹² suggests autotransfusion of blood in the peritoneal cavity when it cannot be obtained from other sources. He has reported such a case with recovery. As an emergency procedure this is justifiable. However, the presence of extravasated bile and the possibility of the contents of a ruptured hollow viscus mixed with the blood in the abdominal cavity, should make this a procedure to be done only after very careful abdominal exploration. Various supportive measures and careful postoperative observations both clinical and laboratory, with prompt attention to whatever complication may arise, are necessary.

Prognosis seems to depend largely on several factors: (1) the amount of destruction of liver tissue; (2) the escape of bile into the peritoneal cavity, which is quite liable to be a contributing cause to a paralytic ileus; (3) the presence or absence of injury to structures other than the liver, and (4) careful attention to any postoperative complications which might arise. It is well to remember that Mann of the Mayo

CASE REPORT

A young white man, aged nineteen, was injured in an automobile accident about 8:30 the evening of April 29, 1928. He was sitting in the rumble seat of a car which collided head-on with an on-coming car, throwing him with violent force against the back of the seat in front. He struck his right chest and right upper abdomen and at once experienced severe pain in these areas. I saw him in about half an hour after the accident at the Mercy General Hospital. His pulse was 74, temperature 98.4°F. and respirations 26. He complained of pain in three distinct locations: (1) the upper right abdominal quadrant; (2) the right chest wall, and (3) the right scapular region. Examination revealed a well-developed young man in moderate shock. There was an area in the upper right abdominal quadrant board-like in hardness and exquisitely tender, a spot in the right anterior axillary line about the seventh or eighth rib was quite painful on palpation and there was a slight laceration of the face which was of no consequence. Urinalysis was entirely negative. The blood count showed a hemoglobin of 90 per cent, 5 million red cells, and 16,000 white cells. Roentgen ray of the chest revealed a fracture of the seventh rib

in the anterior right axillary line with perfect approximation of the ends. Two per cent mercurochrome was applied to the laceration

FIG. 2. Blood urea (in milligrams).

on the face; the chest strapped with adhesive and a period of "watchful waiting" assumed in so far as the abdominal condition was concerned. Mild opium narcosis and a hot water bottle to the abdomen were ordered. During the night the pulse went down to 54 (three hours after the accident) and the patient was restless and in pain. At 11:30 P.M. the white count had risen from 16,000 to 20,000

FIG. 3. Icterus index.

The following morning the pulse was 70, temperature 98.4°F. and respirations about 20. Blood pressure was 120/74. The urine showed a faint trace of albumin and was positive for sugar. The white count was still 20,000. Abdominal pain and board-like hardness were more pronounced. I could not make out a fluid wave. About noon the pain became unbearable. I made a tentative diagnosis of ruptured liver 75 per cent, ruptured hollow viscus 15 per cent and ruptured spleen 10 per cent. Before operating, however, I desired consultation in view of what I considered atypical symptoms. The consultant concurred in my diagnosis.

Exploration was performed at 2:30 P.M. April 30, under morphine narcosis and light ether anesthesia. A high right rectus incision

FIG. 4. Blood chlorides.

was made; there was approximately 1000 c.c. of blood, both fresh and clotted, in the abdominal cavity, this was removed with sponges and the aspirator as thoroughly as possible; the intestines were markedly bile stained; the gall bladder was completely collapsed, but no injury to that viscus or the ducts could be found; the spleen, stomach, duodenum, intestines, pancreas and kidneys were negative for injury; blood was seen trickling down the

FIG. 5. Blood calcium.

anterior surface of the liver, but no rupture was visible; the exploring hand encountered a large rent far up on the superior surface of the dome of the right lobe of the liver; this rupture easily admitted four fingers, which went down into liver tissue against no resistance as far as they could be thrust in a bent exploring position; there was no injury to the diaphragm. Suturing of this wound was absolutely out of the question. The cavity and area between the dome and the diaphragm were packed with about 16 feet of uterine packing which was brought out of the upper pole of the abdominal incision through a Penrose drain. I made a rapid closure completing the operation in about thirty minutes.

The patient left the operating table in fair condition only. The usual immediate postoperative supportive measures were instituted.

Postoperative Course. Reaction from the operation was uneventful. For five or six days his condition remained satisfactory. On the sixth day his condition became worse; jaundice was markedly increased, the abdomen was somewhat distended, and nausea, which heretofore had been about what one would expect following an ether anesthetization, was more pronounced. The patient looked toxic. For eight days he remained in a critical condition, with symptoms characteristic of a severe toxemia of obstructive origin. At the end of the third postoperative week he was well on his way to recovery.

During the critical stage the observations charted below were made, and treatment was based on their findings as well as on clinical observations. This treatment consisted of daily blood transfusions, hypertonic intravenous saline infusions, gastric lavage, practically a pure carbohydrate diet (inclusive of glucose by rectal drip), calcium and parathyroid therapy and supportive cardiac measures.

CLINICAL OBSERVATIONS

1. *Pulse, Temperature and Respirations.*

The pulse dropped to the low reading of 54 in about three hours after the accident in spite of severe intra-abdominal hemorrhage. The highest it went before operation was 80, and then immediately before surgical intervention. The temperature and respirations were about what would be expected throughout his illness, with the exception of the twelfth postoperative day when a subnormal temperature, labored respirations and a mounting pulse rate led me to expect an early death.

2. *Blood Picture.* The hemoglobin dropped to 80 per cent on the day of operation. Six days subsequently it was 52 per cent. Blood transfusions were begun and were given daily, two on the eleventh postoperative day. In spite of nine consecutive transfusions of 500 c.c. each of citrated blood, the hemoglobin dropped steadily to 30 per cent. The red cells dropped accordingly to 1,600,000 while the leucocytes went up to 72,000 with neutrophils over 80 per cent. The fourteenth postoperative day the coagulation time was four minutes and there were 15 per cent of reticulocytes with the red count and hemoglobin at their lowest levels. At no time was

there any appreciable amount of fresh blood on the dressings.

3. *Blood Chemistry.* (a) The blood urea on the eighth postoperative day was 268 mg. per 100 c.c. of blood. Under gastric lavage, hypertonic intravenous saline injections and carbohydrate feedings it dropped to 32 mg. per 100 c.c. in about ten days.

(b) The blood chlorides on the fifth day were 418 mg. per 100 c.c. In a week's time under therapeutic measures outlined it had risen to 430 mg. per 100 c.c.

(c) The blood calcium under calcium and parathyroid therapy rose slowly from 7.5 mg. on the seventh day to 8.5 mg. on the twenty-third day, and finally to 10.4 mg. on the thirtieth day.

(d) The icterus index was 42 the sixth day. With the disappearance of jaundice on about the twenty-second day it had dropped to 5.0. The Van den Burgh test showed an immediate positive direct reaction which became negative in about a month.

4. *Urine.* The urine was entirely normal on admission. The day of operation it showed a trace of sugar and a faint trace the third day. Albumin and granular and hyaline casts promptly appeared and remained fairly constant for three weeks. On dismissal from the hospital, there was a very faint trace of albumin and a rare cast in centrifugalized specimens. Determination of acetone bodies was not done, it is improbable that they were present.

DISCUSSION

The physiological significance of the liver assumes great proportions when we realize that it is located between the intestines and the greater circulation. It is difficult to grasp the complicated functions of this important structure. The researches of Mann and his co-workers at the Mayo Clinic have thrown considerable light on its intricate processes.

It is not probable that the high blood urea is evidence of hepatic insufficiency. Taken with the clinical picture and the low blood chlorides it is undoubtedly evidence of gastrointestinal stasis. The cause of this stasis is undoubtedly twofold: first, the trauma in the peritoneal cavity, and, second, the leakage of bile in the

peritoneal cavity was probably sufficient to produce a paralytic ileus.² This was overcome by the injection of hypertonic sodium chloride solution and gastric lavage. With the recovery from the condition, as evidenced by renewal of intestinal activity, the blood urea dropped to normal.

The institution of a carbohydrate diet is of direct value in cases of liver injury, although the exact mechanism involved is a matter of speculation at the present time. Bollmann³ has found that animals with a greatly damaged liver recover much better on a carbohydrate diet than on diets containing proteins.

The appearance and degree of jaundice was checked with the laboratory observations on the bilirubin content of the blood. The behavior of these tests and the picture of clinical icterus was that of a mild obstructive type of jaundice. The gall-bladder was found to be completely collapsed at operation and much bile was being poured out of the wounded liver. This presented a situation somewhat comparable to a case of obstruction. Blood was being destroyed and accordingly the bile was becoming thicker and richer in pigments so that the ducts could not be readily emptied by the secretory pressure of the liver. The secretory pressure of the liver was necessarily decreased due to the shattering of the right lobe and rupture of Glisson's capsule. Consequently bile was dammed back and forced into the lymphatic channels with a resulting icterus.

An interesting feature is the rapid fall in hemoglobin and red cells in spite of nine blood transfusions, the practical absence of any fresh blood on the dressings and the presence of 15 per cent reticulated red cells. The explanation is closely linked with that of the icterus just discussed. Obviously it was a hemolytic sort of an affair, toxic in origin, a hemohepatogenous jaundice. This is usually referred to as a non-obstructive jaundice, which in reality is not a non-obstructive jaundice at all. There is an obstruction which is shifted from the larger ducts to the small bile

radicles. Many, of course, escape, so that there is not a complete obstruction but a partial one.

The cumulation of urea in the blood may have been associated with renal impairment. Kidney disfunction might have been partially due to trauma, gastrointestinal stasis, jaundice, and also to the destruction of blood both from hemorrhage and from that given in transfusions. As the symptoms of toxemia developed, naturally the kidney showed symptoms of damage: heavy traces of albumin and the presence of numerous casts. It is probable that there was no acidosis as evidenced by the low blood chlorides, high urea and the probability of a high CO_2 combining power. Later the carbohydrate diet would preclude the possibility of an acidosis. The presence of sugar on two occasions early after operation was probably due to shock associated with the accident and the operation. It promptly disappeared.

By the end of the third postoperative week all clinical findings were either normal or rapidly approaching normal. In four months he was back at work, practically recovered from the accident and complications subsequent thereto.

It is interesting to note here that a year subsequently I referred him to Dr. H. C. Shirley of Charlotte for advice as to tonsillectomy. This was performed by him under local anesthesia. Three days after the operation the patient developed a generalized ooze of blood from each fossa, which persisted in spite of entirely normal blood chemistry findings, normal blood coagulation time, normal platelet count and the usual therapeutic measures, until a small blood transfusion was given.¹⁰

SUMMARY AND CONCLUSIONS

The case reported is an excellent one for study in that the only primary lesion of any consequence was that of subcutaneous rupture of the liver. The outstanding clinical features of the case were: (1) board-like hardness in the upper right abdominal quadrant; (2) referred

pain to the right scapular region, and (3) a slow pulse reaching the low count of 54 three hours after the accident in spite of severe intra-abdominal hemorrhage.

Probably the high mortality in crushing injuries of the abdomen, especially those cases in which the liver is ruptured, is influenced to a large extent by the development of a gastrointestinal stasis and resulting toxemia. This stasis may occur as a result of trauma in the peritoneal cavity, or to a leakage of bile into the peritoneal cavity sufficient to produce a paralytic ileus. The case reported and the studies thereon tend to support this idea.

In addition to early diagnosis and proper surgical means for controlling hem-

orrhage, it is essential that complications subsequent to and depending on a gastrointestinal stasis should be anticipated and promptly handled. The use of carbohydrate feeding, hypertonic saline intravenously and gastric lavage is stressed. The attempt on the part of the body to regenerate blood should be assisted by repeated blood transfusions. Observations on the blood chemistry are necessary for proper treatment.

It is well known that the use of spinal anesthesia is very efficacious in the treatment of paralytic ileus; perhaps such an anesthetic would be the anesthetic of choice in these injuries as a possible prophylactic measure.

THE LATENT GALL BLADDER*

WALTER A. BAYLEY, M.D.

LOS ANGELES, CALIF.

FOR the purposes of this paper the latent gall bladder is considered to be the one whose function is impaired or lost, as distinguished from frank gall-bladder disease easily diagnosed, although it will be necessary to make some reference to the latter. Probably 10 per cent of the adult population have more or less disease of the biliary tract and due to the factor of pregnancy 8 out of 10 of them are women. This especially applies after the age of forty. There are thousands of people today, who in the next ten or twenty years will go to the operating table for the purposes of having a diseased gall bladder removed. Following operation many will die, probably 5 per cent according to the present average statistics.

While little can be said for the tonsils and appendix, something can be said for the gall bladder. It is now definitely known that the gall bladder concentrates the bile to about one-tenth of the amount delivered from the liver. This bile is passed on to the duodenum at the proper time during digestion. The gall bladder also regulates the pressure in the ducts and may have something to do with fat digestion. However, it is well known that one can get along without it, in fact with great improvement in health if it is removed following proper indications. Following cholecystectomy the ducts dilate, the sphincter of Oddi relaxes and digestion seems to go on as well as when the gall bladder was functioning normally. However, the functional importance of this organ compared with its great power for evil is insignificant, indeed. Acute and chronic infection with or without stones, perforation with infection of the ducts, pancreas and liver and occasionally cancer, not to mention it as a source of focal infection in myocarditis, anthritis and other diseases, all of these can be caused

by disease of this organ. It is also the most prolific source of indigestion and dyspepsia in the middle-aged adult. The older the individual when operation becomes necessary the greater the risk and the more widespread the infection, oftentimes resulting in only partial relief from cholecystectomy.

It has been aptly said that the stomach is the loud speaker for almost every organ of the abdomen. This is especially true for the non-functioning or poorly functioning gall bladder. The symptoms are essentially dyspepsia during early digestion, during the period when the stomach is mechanically reducing its contents to chyme and the duodenum is emulsifying the material received with the aid of the rapidly discharged concentrated bile. If the proper amount is not received there is abnormal activity in the duodenum with antiperistalsis and pylorospasm. This is clinically manifested by uncomfortable fullness after meals, belching and sour regurgitations. Occasionally there is pain radiating around to the back. The patient finds that he cannot digest greasy, heavy, acid foods and for relief finds it necessary to exclude many varieties of food to which he has been accustomed. These symptoms will most often occur when meals are large, or much rich, sweet food is taken rapidly, or if the diet includes raw fruits, salads and especially fats. Sometimes they follow unusual nervous fatigue. Another type of individual in whom the gall bladder is at fault but often not suspected is the one with few complaints referred directly to the abdomen but many nervous symptoms and much complaint as to head pains. Diagnosis is difficult and mistakes are apt to occur if all other possible causes are not ruled out in this type.

The woman who has borne children and is now approaching middle age should always be questioned as to pain in the gall-

* Read before the Los Angeles Surgical Society, March 8, 1929.

bladder region during the latter months of her pregnancies or shortly after. Often infection starts at this time to remain latent for years afterwards until suddenly an acute cholecystitis develops or a typical gallstone colic occurs. Go into any woman's surgical ward in this country and you will find that almost every obese woman in that ward, barring an occasional umbilical hernia or other type of operation, represents a result of gall-bladder infection. She is there for a gall-bladder operation or for the repair of a hernia as the result of one. Incidentally, if we would look over our postoperative results we would find that postoperative hernia or weakened abdominal wall occurs more than occasionally. Obesity goes hand in hand with gall-bladder infections which have usually been latent for years. The infection flares up when the woman is excessively fat, a difficult subject to operate upon and often not a first-class surgical risk.

In the overweight, middle-aged woman coming in with vague digestive complaints do not forget the latent gall bladder. Only yesterday I operated upon one of these patients, forty-nine years old, mother of ten children, and 70 pounds overweight. The history included many years of obscure digestive complaints variously treated as indigestion and dyspepsia. By standing on a stool so as to get into proper position I was able to remove a chronically inflamed gall bladder completely filled with large stones.

Up until four or five years ago the diagnosis of gall-bladder disease depended upon an accurate clinical history and careful physical examination supplemented by positive x-ray findings in possibly 30 per cent of the cases. A high average of correct diagnoses was made in the fairly typical cases as proved by operation. Now, due to the work of Graham and Cole, a new x-ray technic has been developed so that a positive diagnosis of impaired gall-bladder function is possible in the hands of an expert in about 90 per cent of the cases. It must be remembered that this

test is a functional one and does not demonstrate pathology except in a minority of cases, as when gallstone shadows appear. I believe that this is the most remarkable advance in laboratory diagnosis in recent years. This new method has stimulated increased interest in the diagnosis of gall-bladder disease. Failing to fill is by far the most important sign. This is due to the occlusion of the cystic duct or complete lack of function. This, added to a clear-cut clinical history, makes the diagnosis certain in the majority of cases. Other important signs that may be of value are filling defects due to calculi or irregularities of contour due to pericystic adhesions. Interpretations of variations from normal in filling and emptying time give the most errors in the positive films, probably 5 per cent. The negative cholecystogram at present gives about 30 per cent of errors and should be disregarded if the clinical symptoms point definitely to disease of the biliary tract. However, with ill-defined symptoms and a negative x-ray report, surgery should be withheld until all other causes can be eliminated.

What is to be done about the quiescent or latent gall bladder? Should we rush all of these patients to the operating room as soon as we have determined that the gall bladder is not functioning properly, remembering a 5 per cent mortality and a morbidity which includes postoperative adhesions, ventral hernia and occasional injury to the common duct. Moynihan condemns, every gall bladder to excision if, in the presence of inaugural symptoms, the cystographic shadow is absent, its opacity diminished or its appearance delayed. It must be remembered that the more positive the symptoms the better the operative results, especially if pain is a predominant factor. The converse is also true. I believe that the case diagnosed early before the onset of typical symptoms should first be given the benefit of proper medical treatment.

I would like to say a word as to diet: This should be fat free; all meat fats,

cream, butter, oils, yolks of eggs and cheese are omitted or reduced to a minimum. Coarse vegetables are to be avoided or thoroughly cooked and pureed to reduce motor activity. Raw fruits are also excluded from the diet and the caloric intake is cut down to reduce obesity. This reduces the cholesterol content of the bile and the motor demands on the gall bladder are lessened, tending to a condition of physiological rest, during which inflammation subsides. In the early cases this may be all that is required but too much reliance must not be placed on this method. One or more recurrences will generally indicate surgery.

Besides the usual indications for gall-bladder surgery such as repeated gallstone colics, acute cholecystitis (always surgical when the attack has quieted down), cholangitis and common-duct obstructions, the positive indications for surgery should include symptoms such as nausea, gaseous eructations, abdominal distention, headache and indefinite upper abdominal pain if other causes can be ruled out and thorough medical treatment has failed to bring relief. This especially applies to the overweight middle-aged patient. This should be confirmed if possible by positive x-ray evidence especially failure of the gall bladder to fill or demonstration of the presence of stones. In chronic myocarditis or arthritis when all other sources of focal infection have been eliminated, the removal of a latent, infected gall bladder may bring marked improvement.

Before closing may I briefly consider the contraindications to gall-bladder surgery even in the presence of definite pathology? In general they include severe myocarditis, decompensated cardiorenal disease, advanced nephritis, often diabetes and the severe anemias. Avoid surgery in the elderly patient with angina pectoris, the anginal attacks radiating to the ensiform. Mistakes are liable if the x-ray evidence is positive or a so-called silent stone is revealed. In differential diagnosis remember the relations of pain to exertion and the improvement with rest. Some time ago I was called in consultation on a case of this type, the date for operation already having been set. To avoid embarrassment I suggested calling in a heart specialist to see if the patient could stand operation. The operation was postponed and within a month the patient, while up and about, suddenly dropped dead.

In closing I would like to mention one more type of patient with latent or active gall-bladder disease in whom operation while not contraindicated is exceedingly dangerous. This is the fleshy individual with short neck and short abdominal walls. This patient has a flabby heart and a gall bladder situated deep under the costal arch. People of this type take anesthetics badly and they are subject to shock, postoperative pneumonia and nephritis. When operation is done, local anesthesia with the addition of nitrous oxide or ethylene is the anesthetic of choice.

INJECTION TREATMENT OF VARICOSE VEINS*

RALPH M. CARTER, M.D., F.A.C.S.

GREEN BAY, WIS.

UNTIL recently, the treatment of varicose veins of the lower extremities has been notoriously unsatisfactory. Surgical removal necessitates hospital confinement, requires a more or less prolonged stay in bed, and is not without its dangers. In addition to all this, unsightly scars often result and recurrences are far from infrequent. Under these circumstances, many surgeons do not urge operation, and many patients, unless positively disabled, prefer to endure their discomforts and disabilities rather than submit to a procedure which holds out a somewhat indefinite promise of success. With the advent of the injection treatment, however, the situation has undergone a decided change for the better.

Although comparatively new in America, the method has been in use in Europe for a number of years. The French, German, Scandinavian, and, to a lesser extent, the English literature is voluminous on the subject, and the procedure is everywhere generally accepted and practiced.

HISTORICAL

Attempts to produce occlusion of veins by the injection into them of various substances date from 1851, in which year Pravaz introduced his syringe for the injection treatment of aneurysm. However, due principally to the fact that the solutions formerly used were highly caustic, leading to tissue necrosis and sloughing, and not infrequently to death from septicemia and embolism, the method fell into disrepute and was abandoned.

The present method was originated by P. Linser of Tübingen,¹ Germany. While using mercuric chloride intravenously in the treatment of syphilis, he noticed that the vein after repeated injections became sclerosed and obliterated. He thereupon applied this observation in the

treatment of varicose veins, at first making use of mercuric chloride, later changing to the less toxic sodium chloride. Later, the method was popularized in France by Sicard,² using first a solution of sodium carbonate, and later one of sodium salicylate. Since then, the employment of the injection treatment has become general throughout Europe.

In the United States widespread adoption of the treatment has been rather slow, owing principally, I believe, to the fear of embolism. *A priori*, this fear would seem to be well founded; practically, however, the danger may be said to be non-existent, for reasons which will be considered later. From a statistical stand-point, there are available many figures demonstrating the innocuousness of the procedure; among the most recent are those of McPheeters and Rice.³ These investigators collected reports of 53,000 cases treated by the injection method, with a mortality traceable to the injection of 0.0024 per cent. Linser, likewise, states that he has never observed embolism in over 15,000 injections. These figures are unquestioned; they prove that this method of treatment is one of the safest of surgical procedures.

SOLUTIONS EMPLOYED

Contrary to the belief formerly held, which belief was responsible for the ill-repute into which the treatment fell for a time, strong toxic and coagulant solutions are not necessary for success; consequently, the use of carbolic acid, ferric chloride, tincture of iodine, etc., is no longer practiced nor is it justifiable. The principal substances in use today are sodium chloride, sodium salicylate and various sugars. Mercuric chloride is advocated by some, but its use has been rather limited, due to its toxicity; furthermore it has no outstanding advantages to recommend it. Other

* Submitted for publication November 25, 1929.

drugs which have been suggested and utilized to some extent are sodium citrate, sodium bicarbonate, and quinine and urethane.

Sodium chloride is most commonly employed in the form of a 20 per cent solution. In this concentration it is non-toxic, produces a firm clot, and may be used with a very fine needle, which is an advantage. However, great care must be taken to see that none of it escapes into the surrounding tissues; also, the cramps immediately following the injection are frequently very painful and severe.

Sodium salicylate is injected in a 20 to 40 per cent solution. It is likewise capable of causing considerable tissue damage in case of leakage or of injection outside the vein, and is also toxic to a not inconsiderable number of patients.

Various solutions of sugars are in use, particularly in Austria and Germany: for example, 50 per cent solution of dextrose, equal parts of 50 per cent solutions of dextrose and levulose, which constitutes the mixture known as calorose,⁴ and 75 per cent solution of invertose, or invert sugar. The latter is the one which I prefer for general use. All of these solutions produce excellent thrombi, are much less toxic to the tissues in case of leakage, and the injection is practically painless. However, not infrequently a patient will be encountered who does not react to them, and other substances must then be used. Another minor disadvantage is that concentrated sugar solutions are thick, necessitating the use of a larger needle; this can largely be obviated, however, by warming the solution.

In a recent paper, Kern and Angle⁵ have strongly recommended a mixture of equal parts of 50 per cent dextrose and 30 per cent sodium chloride. They state that following the use of such a mixture, the resulting clot is very firm and tenacious, and that no sloughs are produced if the solution escapes outside the vessel wall. I have had no experience in the use of this mixture.

It should be emphasized that one

cannot confine his treatment to the use of a single solution. The preparations already described all have their advantages and disadvantages; individuals vary in their reactions. If the desired result is not attained by the use of one drug, the operator must be prepared to employ something else. But for general use, as I have just said, in my experience a 75 per cent solution of invertose has proved most satisfactory. A satisfactory sterile solution is readily available, and is furnished in 10 c.c. ampules.

ANATOMICAL CHANGES

The changes in the vein, both gross and microscopic, brought about as a result of the injection, have been exhaustively studied by many investigators, and the findings are everywhere in agreement.

The recent experiments of Kern and Angle⁵ typify these findings. Using various solutions, injections were made into the jugular veins of 28 dogs, which were killed at varying intervals thereafter, and the veins removed and studied both grossly and microscopically. Although the injections were made in a large vein not far from the heart, in which the blood current is swift, and in which considerable negative pressure exists, it is interesting to observe that none of their dogs died of embolism or showed signs of pulmonary infarction.

They record the observed changes in the excised vein segments as follows:

Specimen 1 (48 hours old): There was considerable inflammatory reaction of the tissues surrounding the vein. The vein was reduced markedly in diameter and appeared collapsed. The wall had a dirty grayish color and felt thickened and hard. On section it contained a very firm red thrombus that was not easily dislodged. There was no fluid blood.

Specimen 2 (1 week old): The vein was lying in a bed of fresh scar tissue and was dissected out with difficulty. It was about one-third its original diameter and felt like a solid cord. On section there was a firm thrombus occluding the distal segment. The thrombus was half red and half white and extended

proximally for an inch; it was a tapering mural thrombus.

The 2 and 4 weeks old specimens showed a progressive reduction in the size of the vein and the thrombus, with the ultimate conversion of both into a fibrous cord.

Thus it is seen that the immediate effect of the injected agent is to give rise to an irritation of the endothelium of the vein, with congestion and cellular proliferation. As a result of this aseptic irritation, or chemical inflammatory process, fibrin is deposited in comparatively large amounts, amounts sufficient to occlude the vein in the usual case, and to cause stoppage of the blood stream through it. This takes place within a short time after the injection has been given. Later changes in the weeks following consist in organization and sclerosis of the deposit. Occasionally, particularly in the larger veins, the occlusion may be incomplete, or it may happen that the fibrinous mass may sometimes become canalized, with reestablishment of the lumen of the vessel. The process is thus essentially an obliterating endangitis.

From this brief description, it is readily apparent that the pathological condition produced differs in several important particulars from that present in the condition ordinarily known as phlebitis. In the first place, the reaction is sterile throughout; furthermore, it is rather sharply localized to a definite segment of the vein, the clot is extremely adherent to the vessel wall, no pain or general edema of the extremity is produced, and the final result is to leave the vein as an atrophied cord.

Phlebitis, on the other hand, is usually the result of an infective process; thus it may, and usually does affect large portions of the vein; it also has a decided tendency to spread, frequently extending from the superficial network to the deep, giving rise to edema. The clot is loose; pain is a constant feature. The end-result is entirely different, the vein remaining hard and bulky, with no tendency to atrophy, and extremely susceptible to further attacks of infection.

Finally, and for us this is a most important distinction, phlebitis may give rise to embolism, while the artificially produced, chemical venitis has positively no tendency so to do. As is shown by the experiments already mentioned, a study of the excised segments of affected veins anatomically confirms this clinical fact. In phlebitis, the thrombus is found to be loose and jelly-like, insecurely anchored to the vessel wall; in venitis, on the other hand, it is hard and firm, and very difficult to separate. Microscopically, in the latter condition, the clot is found to be so intimately attached that it may almost be considered as a part of the vessel itself, which is far from being the case in phlebitis.

TECHNIC

For several months past, I have been giving these injections with highly gratifying results. The technic which I employ is as follows:

The usual tests are made to ascertain the competency of the deeper system of veins. With the patient in the standing posture, the leg is carefully examined, and a prominent vein is selected to be injected. A tourniquet is used if necessary to make the veins stand out sufficiently. The skin is washed with alcohol, and the actual site of injection is marked with mercurochrome. This is important, as the veins become less prominent as soon as the leg is elevated. The patient is then placed on a table, lying down, with the head slightly raised. In order to secure a concentrated action of the solution on the inner wall of the vein, it is necessary to occlude for a time the segment of the vessel into which the injection is made. For this purpose, I use an instrument known as the varioccluser. This is an oblong metal ring, 3 inches in its long diameter by $1\frac{1}{2}$ inches in its short. It is provided with a handle by means of which it may be pressed down upon the vein, a segment of which is thus effectually cut off, both proximally and distally. The same result may be obtained by having an assistant use the forefinger

and thumb for compression. For making the injection, I use an ordinary 10 c.c. Luer syringe with a 22 gauge needle; between the syringe and the needle is placed a two-way stop-cock.

The syringe is filled with the solution to be injected, after which the stop-cock is set so that the passage is open from the needle to the exterior, that from the syringe to the needle being closed. With the varioccluser in place, the vein is punctured, and the blood contained in the isolated segment runs out through the stop-cock, allowing the vein to collapse and creating the most favorable condition for the action of the solution on the vein wall. The valve of the stop-cock is then turned so as to open the passage from the needle to the syringe, and the injection is made. Occasionally the pressure in the vein is so low that the blood does not escape; under such circumstances, the valve is turned, a small amount of blood is aspirated into the syringe to be certain that the needle is in the vein, and the injection is then made. No solution should ever be injected until one is absolutely certain that the vein has been entered. Following the injection, the pressure with the varioccluser or with the finger and thumb is maintained for five minutes. A small pad of sterile gauze, held in place by adhesive strips, is placed over the puncture wound, to remain for two or three hours until natural sealing takes place. The patient follows his usual routine thereafter, just as though no treatment had been given.

The amount of solution injected varies, and may be anywhere from 5 to 10, and in some cases, 20 c.c. Enough should be used to fill the isolated segment of vein without causing rupture. In my work, the first injection is usually 5 c.c., regardless of whether the vein is filled or not. I do this in order to test out roughly the susceptibility of the patient's tissues to the solutions used. Following this, if the reaction is more severe than usual, I do not increase the amount of solution at the next injection; otherwise, for the second injection, I employ 10 c.c., and thereafter

as much as needed. For the majority of cases, 10 c.c. is usually sufficient for each succeeding injection.

This, briefly and in general, is the technic which I employ, and by which I have made several hundred injections. It is entirely an office procedure, and causes no disability whatever. Special attention, however, should be called to a few points.

DISCUSSION

I make it a rule to administer the treatment in the morning, or if this is not possible, early in the afternoon, I do this in order that several hours may elapse before the patient goes to bed. The recent experiments of McPheeters and Rice⁶ have demonstrated conclusively that centripetal current in these dilated veins is extremely sluggish, if not entirely absent, especially in the erect posture. During the interval of time just mentioned, the thrombus has an opportunity to become firmly attached before the horizontal position is assumed. Theoretically, the remote chances of embolism are increased by recumbency shortly after the injection; practically, such an accident probably would not take place, but there is no justification for taking the risk. For this reason, injections in bed-ridden patients are contraindicated.

One must be absolutely certain that the needle is within the lumen of the vein before beginning the injection. As was stated previously, the action of some of the solutions used upon the tissues is disastrous, if any escapes the vessel. Particularly is this true of solutions of sodium chloride and of sodium salicylate. The former gives rise to a peculiar blanching of the tissues, and both quickly cause necrosis and sloughing of large areas. When using either of these, a large syringe full of normal salt solution should be kept at hand: in the event of an injection outside the vein, or of extensive leakage, the tissues should immediately be infiltrated freely and extensively with the physiological saline. While this will not entirely prevent the damage, it causes a marked ameliora-

tion. Sugar solutions do not appear to have this harmful effect upon the tissues; considerable reaction may be produced, but necrosis and sloughing rarely, if ever, occur.

Even though the technic of the injection has been perfect, and it is practically certain that no leakage has occurred, not infrequently certain patients are encountered in whom a decided tissue reaction will take place. This is manifested by a considerable area of redness and induration surrounding the site of the injection, sometimes to a distance of several centimeters. This reddened and indurated area is sore and somewhat painful upon palpation. Such a condition need occasion no alarm. The height of the reaction is usually passed within forty-eight hours, although some induration and increased sensitiveness may remain for several days. Hot fomentations are all the treatment that is necessary, and give prompt relief. In patients presenting this marked reaction, it is my custom to lengthen the interval between the injections, in order that the effects of one may be over before the next is given.

In a few cases, I have noted a localized, transient edema below the site of the injection, apparently in the area drained by the vein which has been occluded. This edema is definitely circumscribed and confined to a small area, it is not painful, gives rise to no inconvenience whatever, and disappears spontaneously within twenty-four hours.

Some writers advise the use of an elastic compression bandage following the injection and during the course of the treatment. I fail to see any necessity for this, and have not used it. In my work, as I have said above, I cover the puncture wound with a small pad of gauze, firmly applied and held in place with adhesive strips. This remains in place for a few hours, until natural sealing takes place, when it is removed by the patient himself.

A few words should be said in regard to pain. With proper technic, the procedure is practically painless. When using solu-

tions of sodium chloride or of sodium salicylate, during or immediately following the injection, painful muscular cramps are sometimes experienced; these also occasionally appear when sugar solutions are used, but much less frequently. Such cramps are evanescent, disappearing shortly after the injection has been completed. The tissue reaction already described and which comes on later, gives rise more to a soreness in the structures affected than to actual pain. Severe pain of any considerable duration, especially if in the area immediately surrounding the point of injection, means that the needle has not entered the vein or that leakage is taking place, and the injection should immediately be discontinued.

In regard to the interval between injections, it is my practice in the average case to inject about twice a week, although the treatment may be given every second or third day. In my opinion, the severity of the reaction should determine the interval, and I prefer to wait until this reaction subsides before again injecting: thus, the length of time intervening may be two days, or it may be a week. It should be emphasized that the treatment must be ambulatory, and there is nothing to be gained by subjecting the patient to unnecessary inconvenience.

Not infrequently patients will be encountered in whom the veins collapse to a marked degree upon the assumption of the reclining position, making the injection very difficult of accomplishment. This may occur even though a tourniquet be previously applied. Under such circumstances, the treatment may be administered with the patient standing, the technic being otherwise the same.

It is my practice to inject the upper part of the dilated veins first; when this is done, it frequently happens that fewer injections lower down are necessary, due to the fact that a main trunk has been occluded, leading to a disappearance of many of the collaterals. In no case, however, should injections be given above the middle third of the thigh. As a rule, I make only

one injection at a sitting, although in the case of a patient with varicose veins in both legs, there is no particular reason why both legs should not be injected at the same time, if desired. However, if the patient should be one of those individuals who react strongly to the injected solution, considerable discomfort would probably result. As already stated, the treatment is, and must be ambulatory; consequently any unnecessary pain and inconvenience is to be avoided. I do not consider two injections into the same leg at one sitting at all advisable; as a matter of fact, the only reason for two injections is to shorten the duration of the treatment, and in the most of these cases, haste is in no wise necessary.

The number of injections necessary varies with each case, and with the number of dilated veins. In a few, one or two will be found to be sufficient; the average, I should say, is from six to eight; and finally, some severe cases will require twelve to fifteen. One must be guided by the conditions present, and inject until all prominent veins are obliterated. It is advisable to keep the patient under occasional observation for six weeks to two months following the completion of the treatment; not infrequently a vein will become apparent which was not to be found earlier, and sometimes complete absorption of the thrombus will be found to have taken place, with consequent non-obliteration of the vein. Such cases require further injections.

CONTRAINDICATIONS

Contraindications to the employment of the injection method are extremely few in number. The most important of these is a history of a recent phlebitis. To inject veins which have been the seat of a bacterial inflammation at any time during the preceding year is to my mind a hazardous procedure; preferably the interval should be considerably longer. It is true that some men with extensive experience feel that it is safe to administer treatment after all

pain and evidence of inflammation have completely subsided; for my part, however, I prefer to refuse an occasional case rather than take an unnecessary risk.

And while upon the subject of phlebitis, it must be considered from another important angle. There is no question but that the injected veins may occasionally become the seat of a metastatic infection from some focus elsewhere in the body; such an occurrence is undoubtedly very infrequent, but there is sufficient clinical evidence that it may take place. This being the case, a careful history should be taken of every patient, followed by a thorough general examination; if grossly infected foci are found which are apparently having any decided effect upon the general health of the individual these should be given attention before proceeding with the injections. This has been recently discussed by Kilbourne,⁷ and deserves emphasis.

Other conditions which have been advanced as contraindications are old age, nephritis, and extensive edema of the lower extremities indicating deep circulatory disturbances. All of these, in my opinion, are entirely relative. Old age, in itself, provided the patient is otherwise in good general condition, is no reason for withholding injections; if the general health is enfeebled from some cause or other, however, caution should be exercised as it is, well known that such individuals are very liable to thrombophlebitis. Nephritis, unless advanced, I do not consider a contraindication. Edema of the lower extremities must be carefully investigated. The condition very frequently accompanies dilatation and varicosities of the superficial veins, and under such circumstances, a few injections will cause it rapidly to disappear; on the other hand, if it is due to serious disturbances of the circulation in the deeper system of veins, injections will only aggravate it, if indeed, more serious consequences do not follow.

Varicose ulcers are decidedly not a contraindication, but quite the contrary. Treatment by injection constitutes the

most effective and successful means at our disposal today for the rapid and complete cure of these ulcers.

In the employment of this method, untoward results are possible as follows: (1) from toxic action of the injected fluid; (2) from local injury following the injection; (3) from inflammation of the vein following the injection; (4) from gangrene, and (5) from embolism.

The first four of these possibilities may be dismissed with a few words. With the solutions which are generally used today, toxic action is hardly to be thought of, except in the case of an occasional individual who is susceptible to salicylates; under such circumstances, some other preparation should be employed. With proper care in making the injection, there should be no local injury following it. In this connection, it should again be emphasized that extreme care must be exercised in getting into the vein, because these thin-walled, dilated vessels are more difficult to enter than normal ones. Gangrene is to be avoided by first making sure that the deeper system of veins is competent.

EMBOLISM

As to embolism, increasingly large numbers of statistics clearly demonstrate that its occurrence following proper injection treatment of varicose veins is much rarer than following operation for the same condition. In these cases, the tendency toward embolism appears primarily to be very slight, and whatever danger exists may be reduced to a minimum and the operation rendered entirely safe by attention to a few principles, as follows:

To begin with, the cases should be properly selected. Patients presenting themselves with veins as large as the thumb or larger are not suitable for this form of treatment, and should be rejected.

The treatment must be ambulatory. This means that the injections must be given eight or ten hours previous to the patient's usual time for retiring; following the injection, he should be instructed to

proceed about his usual daily routine, just as though no treatment had been given.

Injections above the middle third of the thigh are to be avoided.

The first injections should be made as high up as possible in the vein.

Finally, a small amount of fluid should be used for the first injection, in order to ascertain the patient's reaction.

If these principles are observed in all cases treated, no danger of embolism need be feared.

SUMMARY

From a considerable study of the literature, and from my own experience, I am convinced that the injection treatment of varicose veins is the best and most successful treatment for this condition which we have at our disposal today. It has the additional advantage of being purely an office procedure and of causing no interruption to the patient's usual routine; consequently it deserves to be widely employed. In this short paper, I have not attempted to be exhaustive; I have merely tried to describe a technic for administering these injections which I have found to be simple and practical, and which, with ordinary care and attention to detail, can be readily utilized by any physician interested in doing this work.

INCONTINENCE OF URINE FROM ABERRANT URETER

REPORT OF A CASE*

B. Z. CASHMAN, M.D.

PITTSBURGH, PA.

OF THE many causes of incontinence of urine in the female, one that is quite rare but satisfactory from the standpoint of treatment, is the opening of an aberrant ureter into the vestibule of the vagina. This condition is of course due to a developmental defect and should be borne in mind and sought for in every case of unexplained incontinence, as the cure of the incontinence is dependent on the correct diagnosis and appropriate surgical treatment. Aside from the occurrence of this condition in gross abnormalities, such as absence of the bladder, monstrosities, etc., the first published clinical report that we have been able to find was by Baker in 1878. He recognized the condition and successfully treated it by implantation of the aberrant ureter into the bladder by way of the vagina. Baker thought that he had a unique case but learned from Jackson of a similar case in Boston City Hospital in 1870. He secured the record of this case and included it in his report. Hartman in 1913 reported 21 cases with ureter opening into the vestibule, and Begg in 1927 has reviewed the literature on the subject in an article on "Incontinence of Urine of Renal Origin" in which he reports a case of aberrant ureter opening into the urethra, and has collected all cases reported of ureters opening into the vestibule or urethra. Of those opening into the vestibule, he found 50 cases. I have found 5 additional case reports as follows: Hayward 1, Juvara 1, Winter 1, Kilbane 2. I wish to add to those reported another case of this anomaly.

Case Report. (Gynec. No. 1010.) Sr. E. Aged sixteen. St. Francis Hospital, Admitted December 29, 1927. Chief Complaint: Leakage of urine.

History. Patient states that as long as she can remember there has been enough leakage of urine to soil her clothing slightly. In the last three years this has been more marked, and patient finds a spot in the bed in the morning. She voids regularly and normally and has no frequency, burning, nor pain on urination.

Menstruation began at fifteen, has been irregular, sometimes flowing twice in one month. Flow lasts five to six days and menstrual cramps are present at times. Last period began on December 27, 1927, and patient is still flowing (two days). No leucorrhea.

She had scarlet fever at nine, but no other serious illness. No operations. There is no history of congenital defects in the family.

Physical Examination. Patient is very shy and retiring and it is difficult to get a good history, as she is ashamed of the ailment. She was brought to the hospital by her associates who stated that the urinous odor was very marked. There was nothing of note found in the general physical examination. No tenderness in region of kidneys. The urine was negative for albumin, sugar, blood and pus. Wassermann negative. On vaginal examination, hymen was intact. On rectal examination, the uterus and adnexa felt normal. Bladder was catheterized and clear urine obtained. Five tenths cm. below external urethral orifice and slightly to the right of the midline, drops of clear fluid were seen escaping at intervals from a small orifice which was visible as a small slit, but which gaped when the fluid was escaping. This resembled a ureteral orifice in the periodic escape of a few drops of fluid. There was no steady drip and at times the intervals were quite long between the discharge of the fluid. Attempts were made to collect sufficient fluid for examination but very little could be obtained. It was clear, and on microscopic examination no pus cells were found. Attempts to pass a small probe into the orifice were not successful, but a No. 5 opaque ureteral catheter was finally inserted for a distance of 4 cm. A few drops of clear fluid came through the

* Presented as a thesis for admission at the Forty-first annual meeting of the American Association of Obstetricians, Gynecologists and Abdominal Surgeons, Toronto, Ont., September 10-12, 1928.

catheter. With the little finger in the vagina, through the unruptured hymen, the catheter could be felt below and to the right of the

catheter placed in the vagina, a photograph was made (Fig. 1).

The x-ray pictures show a very tortuous

FIG. 1. Two No. 7 ureteral catheters in right and left ureters are shown coming out of urethra. Below and to right of external urethral orifice is shown a No. 5 ureteral catheter in anomalous opening, in vestibule, of one component of double right ureter. Other component opens into bladder. Below this is shown a rubber catheter which has been inserted into vagina through unruptured hymen.

urethra. 1 per cent mercurochrome was injected through the ureteral catheter, and the catheterized urine from the bladder, following this procedure, was clear and showed no trace of the dye, from which we assumed that there was no communication with the bladder. No dye escaped from the vagina. Twenty per cent sodium iodide solution was then injected and x-ray plates made. The following day, patient was cystoscoped and bladder mucosa found normal, and right and left orifices found in the normal positions. No. 7 catheters were readily passed into the ureters and No. 5 catheter again inserted into the anomalous opening, and kidney function test with intramuscular injection of 1 c.c. of phenylsulphonaphthalein was done. The dye appeared on the right side in fourteen and one-half minutes and on left side in fifteen minutes. There was no flow from the catheter in the anomalous opening, so that the appearance time of dye could not be determined. Five cubic centimeters of sodium iodide solution was then injected into each catheter and allowed to remain until x-ray plates were made. With ureteral catheters in place and a soft rubber

FIG. 2. Shows opaque ureteral catheter in tortuous passage where obstruction was encountered 4 cm. from orifice. Branching off from this is ureter which seems to end in an ovoid dilatation. Ureter is actually dilated all way to kidney but is filled with urine and opaque fluid reaches only lower part of dilated portion.

passage containing the No. 5 opaque ureteral catheter which seems to end in a blind passage (Fig. 2). Near the upper end of this passage and branching from it is a normal looking ureterogram extending up the right side of the region of the brim of the pelvis where it ends in an ovoid dilatation. Figure 3 shows this to be distinct from normal right ureter. The ovoid dilatation in the region of the brim of the pelvis gave the impression that this was a case of normal bilateral kidneys and ureters and a third ectopic kidney in the pelvis with a ureter that opened into the vestibule. As only a small portion of the urinary output escaped through this orifice, it was felt that it was an unnecessary nuisance and operation advised for removal of the pelvic kidney.

Operation. January 7, 1928. Before operation a No. 7 catheter was placed in the right ureter as a guide. Under spinal anesthesia, abdomen was opened through low midline incision, the intestines were lifted and gauze pad placed so as to hold them out of the pelvis. It was noted that the cornua of the uterus were

prominent, with a tendency to bicornuate uterus. Tubes and ovaries were negative. Beginning about 1 inch above the base of the

FIG. 3. Pyelograms and anomalous ureter. Photograph fails to show what can be seen on x-ray plate that two ureters on right side are distinctly separated as is indicated in accompanying sketch (Fig. 3a).

F.G. 3a

right broad ligament and coursing upward over the brim of the pelvis was a bluish colored, retroperitoneal, elongated sac about 2 cm. in diameter. It was somewhat tense and was

recognized as a dilated ureter. It lay directly over the right ureter in which could readily be felt the ureteral catheter. The peritoneum was incised over the dilated ureter and reflected back. A plexus of veins surrounded the dilated ureter. The ureter narrowed from above downward in a spindlelike manner to about 1 inch above the base of the broad ligament where it was found to be normal in size. The ureter was not opened to determine if there was a stricture here. The dilated portion could be traced upward to the level of the kidney. The lower half of the kidney was slightly larger than normal and felt normal in every way. The upper one-half of the kidney was smaller and more firm and irregular as though cirrhotic. A diagnosis was made of double kidney and ureter, the ureter from lower pelvis opening into the bladder and the ureter from the upper pelvis opening into vestibule of the vagina. As the urine was clear and showed no evidence of infection, excision of the dilated portion of the ureter and upper one-half of the kidney was not thought to be necessary, so the ureter was ligated and divided, below the dilated portion, near the base of the broad ligament where the ureter was normal in size. Through a small muscle splitting incision, a rubber-tissue-drain was carried extra-peritoneally to stump of ureter (probably an unnecessary precaution). The incised peritoneum over the dilated ureter was sutured. The appendix containing a large fecolith causing a fusiform swelling at the tip, so the appendix was removed and midline incision closed without drainage. The rubber-tissue-drain was partly removed in three days; and entirely removed on the fourth day, and patient made an uneventful recovery. There was no incontinence of urine after operation and no pain in region of right kidney.

COMMENT

The interesting features of this case are:

1. The relatively small amount of total urinary output that escaped by way of the aberrant ureter, sufficient only to soil clothing in the day and leave a small spot in the bed at night.

2. The upper dilated portion of the ureter, filled with urine, could not be reached and emptied with the ureteral catheter, so that the injected sodium iodide solution produced a sense of fulness

in region of kidney as though the kidney pelvis were filled, but actually reached only the first portion of the dilated ureter. The ovoid shadow produced here simulated a dilated pelvis of a pelvic kidney.

3. The absence of infection permitted ligation of the ureter as the only operative procedure necessary for the relief of the incontinence. The dilatation of the ureter in this case began higher than is usual in the cases reported. Whether it was a congenital dilatation of the ureter or a stricture of the ureter with dilatation above it, or a valve such as was found by Hunner was not determined, as the ureter was not opened nor excised.

ETIOLOGY

In incontinence due to the ureter opening into the vestibule, there may be a single kidney and ureter on the side involved, but more commonly (in 91 per cent of cases reported) there is a double ureter, the one opening into the bladder and the other into the vestibule. Usually the kidney and ureter of the other side are normal, but in some cases there is double ureter on both sides.

Double ureter is not uncommon but, as a rule, both openings are in the bladder and give rise to no clinical symptoms. Occasionally, however, one component is extravascular and is the cause of the incontinence here considered associated with normal micturition. This anomaly may occur in both sexes. The most satisfactory explanation for this condition was found in Begg's article and illustrated by Figure 4. According to Felix the upper part of the bladder is formed normally from the ventral cloaca, while the trigone is formed from the expanded lower portions of the Wolffian ducts, from the dorsal surfaces of which the original renal buds or future ureters develop. As the Wolffian duct lengthens, after the formation of the trigone, the loop of it passes down internal to the ureter, expanding as it goes, and part of its walls form the urethra and

vestibule. When development is complete, it remains in position as Gärtner's duct. If the renal bud is placed high, the trigone

FIG. 4. Diagrams illustrating how lower ureter may open into bladder, and upper ureter into urethra or vestibule. Portions of wall of expanding Wolffian duct form trigone, urethra and vestibule as indicated by dotted line in lower diagrams:

A.L., Allantois; R., rectum; UR. 2, upper ureter; V.C., ventral cloaca; W.D. Wolffian duct; C.M., cloacal membrane; UR. 1, lower ureter; U and V., represent the portions that will form urethra and vestibule.

may be formed from the expanded lower end of the Wolffian duct before the portion from which the ureter springs has descended and the ureter may then finally open into the urethra or vestibule, depending on which of these structures are formed from the portion to which the ureter is attached. If it is placed so high that descent of the Wolffian duct has ceased before the part to which the ureter is attached is used in the formation of the vestibule and urethra, it then opens into Gärtner's duct and the flow of urine may keep Gärtner's duct patent. This may be the true condition in many cases of aberrant ureters discharging their contents into the vestibule. In the case reported here the marked tortuosity of the canal for $1\frac{1}{2}$ inch within the orifice as shown in Figure 2, the course of the opaque catheter the tip of which seems to end blindly, while the ureter seems to branch off from the side of the canal, is

evidence in favor of the theory that the distal portion of the canal is Gärtner's duct and not the true ureter in this case.

In double ureter two renal buds arise from the same Wolffian duct. Usually, they lie close together and open close together in the bladder. If one arises much higher than the other, the lower one may open into the bladder at approximately the normal position, while the upper one later descends to open into urethra or vestibule. This explains why the ureter with extravesical opening always comes from the upper pelvis of the double kidney.

PATHOLOGY

Of the 56 cases reported, including the one reported in this paper, with termination of ureter in vestibule, 5 were single ureters, and 51 were components of double ureters. The right side is more commonly involved than the left, and the opening is usually to one side of the midline, thus indicating from which kidney the ureter comes. The opening usually lies at the edge of the external urethral orifice or a short distance from it as in my case. (Fig. 1.) It is round or slitlike and usually quite small so that it is difficult to pass a probe or a small catheter. On passing a catheter, obstruction is often encountered from 1 to 2 inches from the orifice. This has been attributed to stricture, or angulation of the ureter due to fixation near the normal site or entry of the ureter into the bladder, or possibly to the ureter entering a patent Gärtner's duct, which was strongly indicated in my case. The ureter is usually dilated due to stricture at the orifice, or strictures higher in its course. Through the vagina it is possible to palpate the dilated ureter as a cystic swelling, in many instances. As this anomaly usually occurs with double kidney and ureter, it is the rule, as one would expect from the embryology, that the ureter with extravesical opening arises from the upper kidney pelvis. The urine is usually infected and this is important in regard to treatment. Function

is decreased in the portion of the kidney involved, as a rule.

SYMPTOMS

The characteristic symptom is incontinence, day and night, along with normal micturition. As the kidney function is usually below normal and as the ureter is usually dilated and acts as a reservoir, the amount of urine escaping is often small in amount and quite variable as to time and quantity. It may be influenced by posture, exercise, etc. There may be pain in the region of the kidney due to back-pressure or infection. Urinous odor and irritation of mucous membrane and skin of vulva and thighs is common. This type of incontinence in the female may be due also to an aberrant ureter opening into the urethra, but is more common in the vestibule ($3\frac{1}{2}$ to 1). In the male, the aberrant ureter opens into the prostatic urethra, seminal vesicle, or vas deferens. As these openings are behind the external sphincter, there is frequency of urination, but not incontinence as in the female.

DIAGNOSIS

Many of these cases are undoubtedly missed because the condition is not borne in mind as a cause of incontinence. The characteristic type of incontinence should call attention to the possibility of this condition and a search made for the extravesical orifice. Preceding the examination the patient should be given large quantities of water in order to increase the flow of urine, and then a careful inspection of the vestibule should be made for the escape of urine. Since the intervals between the discharge of urine were quite long in the above case, several examinations may be necessary where the condition is suspected. As the incontinence may be due to the ureter opening into the urethra. Furniss has recommended the insertion of wet cotton pledgets into the urethra, the vagina, and the vestibule following the injection of indigo-carmin, to determine from which of these three sites the colored

urine escapes. After locating the orifice it will be noticed that urine escapes intermittently as from the ureteral orifice in the bladder, but often with less regularity. On vaginal examination it may be possible to palpate the cystic dilatation of the ureter above the external orifice. If the orifice lies to the side of the midline it indicates that the ureter comes from the side in which the orifice is located. It may be necessary to dilate the small orifice in order to introduce a small ureteral catheter. Injection of sodium iodide followed by x-ray examination is a valuable aid in determining the side involved, the course and degree of dilatation of the ureter, and the form of the kidney pelvis. It must be remembered, however, that if it is not possible to pass a catheter far enough to empty the dilated portion of the ureter, the x-ray examination may be confusing. This was true in my case where it was not possible to pass the catheter more than $1\frac{1}{2}$ inches. The ureter was dilated and tense with retained urine above this portion, so that it was not possible to inject the sodium iodide solution to the kidney, and the x-ray pictures gave the impression of a third kidney at the brim of the pelvis (Fig. 3). Similar apparent sacculations were found by Kilbane and also by Low and Epler, due to stricture above. This should be borne in mind before assuming that there is a third kidney present. Except for the difference in location, Herbst's skiagram of a rudimentary upper pelvis is very similar to the skiagram of dilatation of the ureter shown in Figure 2.

On cystoscopic examination, the presence or absence of a ureteral orifice on the corresponding side of the trigone determines whether the aberrant ureter is single or a component of a double ureter. If the latter, the function and the presence or absence of infection in this portion of the kidney emptying into the bladder can be determined. Simultaneous ureterograms of each component will determine the relation of the aberrant to the normally placed ureter. The urine from the aberrant

ureter should be examined for pus and microorganisms.

TREATMENT

Various procedures have been used to cure the annoying incontinence and at the same time preserve the kidney or portion of kidney involved. In case of single ureter with good function of the kidney involved, implantation of the ureter in the bladder is indicated. Implantation by way of the vagina has not proved very satisfactory and has frequently resulted in vesicovaginal fistula, requiring multiple operations. Judd advocates abdominal extraperitoneal implantation as more satisfactory. He performed this operation in the presence of infected urine, and with careful after-treatment and lavage of kidney pelvis obtained a fairly satisfactory result.

In the absence of infection in a case of double ureter, ligation of the aberrant ureter is sufficient for cure. In the case here reported this was done through the abdomen. A catheter in the normally placed component of the double ureter was a valuable aid in differentiating it from the aberrant component. It is much simpler to ligate from below by dissecting out and resecting the lower end of the ureter by way of the vagina. Kilbane and Furniss both doubt the advisability of ligating the ureter in any instance. In the case above reported where the function of both kidneys emptying into the bladder was good while that of the portion of the kidney secreting through the aberrant ureter was much below normal, the ureter was dilated high up, possibly due to stricture, and the urine was not infected, ligation was simpler and surer than implantation into the bladder, and less formidable than resection of the kidney. To satisfactorily implant the ureter into the bladder in this case, it would have been necessary to open the ureter in the dilated portion and dilate the ureter below this level to overcome stricture before implantation into the bladder. It is also true that

implantation has not been altogether satisfactory. Some of the cases could not be catheterized after a few months and function ceased, due to contracture of the orifice, so that in the end the result was practically a ligation.

Unfortunately, most of the cases are not so favorable for ligation as the one here reported. The usual case is one in which the ureter is dilated, the kidney function impaired and infection present, and with a normal kidney on the other side nephrectomy is usually done, either removal of the entire kidney or resection of the upper portion with its pelvis and dilated ureter. The latter procedure is probably the one of choice in most cases. A sulcus usually marks the limitation of the upper pole, and by a wedge-shaped incision at this level, the upper pole may be excised. Care must be taken to preserve the blood supply of the remaining portion of the kidney and this operation is best performed when each portion of the kidney has an independent blood supply.

SUMMARY

1. There is a type of incontinence of urine in the female, associated with normal micturition, which is due to the opening

of an aberrant ureter into the vestibule or urethra.

2. The aberrant ureter may be single, but there is usually a double ureter, one part opening into the bladder and the other outside of the bladder.

3. The aberrant ureter is usually stric-tured, dilated, infected and associated with the upper half of the kidney with impaired function.

4. The diagnosis is made by the character of the incontinence, the finding of the external orifice, and cystoscopic and x-ray examinations.

5. The treatment is implantation of the ureter into the bladder, ligation of the ureter in clean cases, or in the majority of cases resection of the infected kidney or portion of kidney.

OSTEOMYELITIS*

H. W. CHAPPEL, M.D.

LOS ANGELES, CALIF.

OSTEOMYELITIS is an inflammation of the marrow of the bone, and may be acute or chronic. Its point of origin depends on whether the bone infection is primary or secondary. When bone suppuration results from compound fractures or punctured wounds, it begins at the point of inoculation, but when it is caused by bacteria, usually *Staphylococcus aureus*, conveyed from some focus of infection to the bone through the blood or lymph vessels, it ordinarily begins in the juxta-epiphyseal region. The rapidity with which the invading bacteria destroys the surrounding bone, depends largely on their virulency, the resistance of the surrounding tissue, and the ability of the pus to escape from its point of origin.

In the primary cases the portal of entry frequently remains open, providing a most favorable type of drainage with repair proportional to the amount of mechanical, but non-destructive cleansing of the minute areas of the infected bone. However, in the secondary there is a very different situation with the acute cases. The blood current in the sinus-like vessels is slowed at the seat of election for this disease. Then some slight injury is sufficient to produce in the delicate epiphyseal tissue a bruising of the vessels and an effusion of blood which temporarily interferes with the nutrition of the part. Minute fractures of the bony trabeculae are frequently found after such injuries. At these points the bacteria which may be circulating in the blood move in a comparatively confined vascular area, and readily find lodgment in the bruised tissues or the blood clots.

Where the pathological process originates, the tissues are very unyielding and this greatly favors a rapid spread of the inflammation through the Haversian canals, through which the blood vessels

pass. Swelling, which is the saving and essential characteristic of inflammation, cannot take place in the bone in osteomyelitis. As soon as the limit of expansion in the marrow is reached, the products of inflammation next exert themselves on the internal blood supply of the bone. The blood vessels are quickly occluded, the nourishment of the bone lying within the periosteum is cut off, the circulation being supplanted by stasis and coagulation. This dead structure is rapidly infected, resulting in necrosis and abscess. Pus under pressure is the most dangerous thing in the animal organism, and this exists in acute osteomyelitis as in no other disease. It is one of the most serious of diseases. Loss of life is common, permanent disability may be expected in a large percentage of cases, and bone destruction in every case.

The clinical picture is that of a severe illness, often beginning with delirium and prostration before evidence of affection of any bone. There may be rigor, general illness, severe headache, vomiting, rapid pulse, pain in the limbs, and sometimes convulsions. The temperature is septic, often going to 104°F. There is a marked leucocytosis. Pain is intense in one or more of the bones. Any movement of the neighboring joint or jarring of the limb causes agony. Intense tenderness can be produced by the most gentle pressure. A tap on the bone some distance from the maximum point of tenderness will cause severe pain at that point, but no discomfort where the tap was made. Swelling is not an early sign, and that with redness appear only after the moment for advantageous treatment is long passed. In the early diagnosis of the disease the roentgen ray is of no value.

The differential diagnosis is of upmost importance. In acute rheumatism the pain

* Read before the Los Angeles Surgical Society, February 8, 1929.

shifts from place to place, rigors are absent, the lesion is in the joints and is multiple, heart affections are early and the lesion never leads to suppuration. In acute osteomyelitis, on the other hand, the pain is constant in one spot, rigors are present, the lesion is in the bone and is usually single, heart affections are late, and the lesion leads rapidly to suppuration. In cellulitis the bone itself is not tender and the movements of the extremity, though painful, are free. With erythema nodosum over the tibia the patient has good health, free movement of the part, and there is a peculiar purplish appearance to the part. It is more difficult to differentiate from scurvy, rickets and acute periostitis which have a whitish, somewhat edematous appearance of the skin and superficial tissues. Also movements are painful and bones are tender on pressure and frequently limited to one bone at first. Fever is absent and other signs of rickets are present. Erysipelas over the tibia gives signs closely resembling acute osteomyelitis.

The prognosis should always be guarded. By early recognition and thorough treatment much illness is prevented, necrosis limited, formation of persistent sinuses often prevented, and the patient is comparatively soon out of danger.

There is only one treatment and that is operative. At the point of maximum tenderness expose the bone and evacuate the pus either by the removal of a generous piece of bone or by drilling several holes. Many methods may now be employed for drainage and to aid bone and tissue regeneration. The one which gives the greatest mechanical cleansing, with a non-irritating solution, or pack, generally gives the more rapid, and more often permanent healing. Those most widely used now are the Carrel-Dakin and the Orr vaseline packs with immobilization of the part. Since 1919 I have used the Taylor¹ liquid-tight appliance with most excellent results.

¹I have followed closely the teachings of Drs. W. H. and N. B. Taylor of Toronto, Canada, in the use of their liquid tight appliance, and I make no claim of original work while using it.

After evacuation of the pus destruction ceases. Such portions of the periosteum and medulla as have retained their vitality resume their bone-forming functions. A covering of new bone is now being formed around the area of necrosis and is called the involucrum. This is perforated by apertures called cloacae, through which pus flows profusely. The dead bone which lies adjoining, or within, the involucrum is a marked stimulant to the surrounding tissues. When it is finally completely separated from the living bone, largely through the activity of the osteoclasts, it is called a sequestrum. This may be a part of the outer covering of the diseased bone, and, if left alone, may be expelled through the fistulous opening in the integument. Not infrequently large fragments of bone may be extruded in this way. If the sequestrum has become imprisoned within the wall of new bone, it will be necessary to remove a piece from the wall large enough for the removal of the dead bone.

We have now come to one of the most difficult problems in surgery, that of chronic osteomyelitis. The type which has just been described follows the acute or subacute and is caused by the pyogenic organisms. Another type is Brodie's abscess. It is a small, circumscribed, cold abscess in the shaft of long bones and its etiology is not definitely known. Still another type is chronic (non-suppurative) hemorrhagic osteomyelitis. It begins in the same areas of bone structure as the acute form. The process of bone disintegration is very slow. It follows injuries of moderate or even slight severity.

The lesions of tuberculosis of the bones with their accompanying abscesses are very familiar to every practitioner. However, we must differentiate that lesion from those closely resembling it, so that we will make the mistake of taging every chronic abscess of a bone with the diagnosis of tuberculosis.

Congenital syphilis causes bone lesions which are constantly being treated for

tuberculosis and with disastrous results. A negative Wassermann reaction should not rule out congenital syphilis.

Bone cysts and tumors frequently resemble chronic osteomyelitis.

The discussion of treatment will be confined to that of chronic osteomyelitis caused by the pyogenic organisms.

Many different treatments were used for a few months or years, and given up because of their failure to accomplish what its originator claimed for it. Many cases did not heal. Of these which did heal many broke down afterwards, leaving sinuses communicating with cavities in the interior of the bone. Attempts were made to completely sterilize the abscess cavities with some strong antiseptic, as pure carbolic acid, followed by alcohol, after using the chisel or curette. Frequently this caused a superficial necrosis, resulting in the formation of another sequestrum. Many investigators are hoping to find an antiseptic that will sterilize the abscess cavity and not damage the tissues. For some time it was thought that Dakin's solution with Carrel's technic had solved the problem. I have given the method a fair trial and I do not believe there is any particular advantage in it, or that it is the use of the antiseptic that materially influences the course of the disease.

Still believing that if the cavity could be thoroughly cleansed and filled with a foreign body which would prevent further necrosis and stimulate osteogenesis, the following methods were tried. Most of them have been discarded because they met with too high a percentage of failures.

Following the experiments of Lister, that sterile blood clot rapidly undergoes organization, being converted into new bone in two or three months, several investigators sterilized the cavity with a strong antiseptic and immediately sutured the periosteum, muscles and skin. The results were varied.

The bismuth-iodoform paste of Morison was lightly packed in the cavity and a rubber drain used for forty-eight hours.

Beck's bismuth and vaseline paste has met with a varying degree of success, and is still quite extensively used. Cavities have been filled with bone dust, bone fragments, or the decalcified bone chips of Senn, but met with a high percentage of failures because of the presence of sepsis in the cavity.

After an attempt at sterilization, Hamilton, filled the septic cavities with pieces of sponge, but with poor results. Iodoform gauze, antiseptic cotton, catgut, and other organic substances have been used to obliterate the cavity after an attempt at sterilization, all meeting with frequent failure.

Many successful cases have been reported from the use of the pedunculated flaps of fascia or muscle which have been allowed to fall into and practically fill the cavity. Here the living flap rapidly adheres and supplies the much-needed nourishment, not only for osteogenesis, but for combating the remaining infection. The vitality of these flaps is not interfered with by the presence of mild infection.

The older methods of simple or multiple incisions with rubber tubing or gauze drains and moist dressings, the continuous bath kept at about 102°F. or the wide open wound packed lightly with moist dressings, are still in use and meeting with an encouraging percentage of success.

There have been many failures and a few brilliant results following extensive subperiosteal resection. The operation, both immediate and delayed, should be strongly condemned. However, when a long bone has been destroyed, or the shaft of the tibia removed for necrosis, a fibula has been successfully used to fill the gap.

As the Carrel-Dakin method completely neglects the numerous small pockets of pus leading off from the main cavity, the infection frequently spreads, necessitating an early re-opening of the abscess cavity.

It is not the value of any antiseptic solution, but the thorough mechanical cleansing and greatest possible dilution of the septic agent, that allows an abscess

cavity to completely heal. That is why I gave up the Carrel-Dakin method nine years ago, and have used the Taylor liquid-tight method since then. By means of a liquid-tight appliance, a wound may easily be inundated to its remote parts. Although any solution may be used, a 5 per cent salt solution gives most excellent results. Because of its osmotic character it opens the way to the hidden pockets causing cleansing and healing the same as in the main cavity. Usually after thirty-six hours the suppurative processes have been brought to a standstill by carrying the pus away as soon as it is formed, and rendering the bacteria inert through dilution.

When the level of the fluid in the supplying reservoir is 18 in. above the surface of the wound, the fluid will continue to flow until the wound and all its offshoots are inundated. Then the flow will cease and the pressure becomes equalized throughout all parts of the system. There is nothing violent about this fluid pressure. It is a gentle but very insistent seepage which occurs, probably taking several hours for the fluid to permeate all depths of a wound. The pus mixes freely with the irrigating fluid, and after the seventh cycle there will be a dilution of one in several millions, which is one of the most valuable aids in removing infection and allowing healthy granulations to form. A cycle is usually the inflow (positive pressure) for one hour and the outflow (negative pressure) for fifteen minutes.

The negative pressure established hyperemia and lymphorrhea, which are of greater importance than the thorough cleansing of the cavity.

Heat, which is often necessary to promote an adequate reaction in a wound, can be used to any temperature which the surgeon feels is to the best advantage for healing. The temperature of the fluid may be raised each time a fresh supply is run in from the reservoir.

The salt solution does not water-log the tissues. On the other hand, it has strong

osmotic properties, rapidly reducing swelling and drawing bacteria from remote pockets, where other solutions could not reach them. In long-standing cases the bacterial count usually increases markedly during the early stages of the treatment. It then drops rapidly to its previous level, then to a very few or none, in several fields. Swelling and tenderness disappear very rapidly. The thick exudate of pus changes to clear serum in from three to seven days. The appliance is then discontinued. A closed sterile safety-pin for drainage, and dry sterile dressings changed daily, is all that will be necessary.

If the exudate changes to pus before healing takes place, repeat the irrigations for two or three days. It has been a dictum for ages, "where there is pus let it out." Dr. Taylor says, "ebb and flow irrigation goes a step further and insists: where there is pus wash it out and keep it washed out."

In Dr. Orr's own words:

The proposition upon which the treatment of wounds by drainage and rest was worked out as follows:

1. Primary asepsis or antisepsis to reduce the focal infection. It is not attempted to remove all infection or all diseased tissue. The patient is relied upon to take care of a part of his infection if he is properly assisted and protected.

2. Adequate drainage.

3. A postoperative dressing or method that will protect the wound and the injured or diseased part so that the wound and the part are at rest and there is no opportunity for re-infection.

4. Immobilize so that movement, pain, and muscle spasm are entirely relieved.

The exact technic is as follows:

1. Make a fairly large incision over the infected bone area. Spread apart the skin, muscles, fasciae, and periosteum just far enough to afford access to the diseased area and no farther.

2. Chisel a window into the affected bone area large enough so that all diseased bone may be removed and so that there are no overhanging edges of bone over the diseased area. (Less extensive in acute cases.)

3. Clean out the diseased area gently with a curette or gouge, being careful to refrain from unnecessarily damaging the tissues undergoing repair.

4. Dry the wound and wipe out with 10 per cent iodine followed by 95 per cent alcohol.

5. Pack the entire wound wide open but not tightly with a sterile petrolatum gauze pack. Cover this with a dry sterile pad and bandage on.

6. Apply a plaster cast.

7. Finally, the cast is not to be split nor are windows to be cut in the cast until the wound dressing becomes necessary, which may not be required for several weeks. Complete healing may be obtained with a few dressings at intervals of from ten days to four weeks.

As all the orthopedic services at the Los Angeles General Hospital have been using the Orr treatment during the past two years, I shall give a brief summary of the results. There have been about 50 cases during that time. Five chronic cases were healed in from three to five months. The last one left the hospital about six months ago and so far there has been no recurrence. They were packed on an average of from two to four weeks. If they were not draining very much then only once in two months. The longest chronic case is of

nineteen months' duration, is still in the hospital, not healed but greatly improved.

The acute cases, including an acute recurrence of an old osteomyelitis, healed in from four to seven months with a few recurrences. One acute case which was in the hospital fifteen months left two weeks ago, apparently completely healed.

The conservative management of chronic osteomyelitis will prevent, far more frequently than radical procedures, the miserable train which follows prolonged infection, that of ankylosis or restricted movement of joints, destruction and sclerosis of muscle, necrosis and non-union of bone, to say nothing of lowered morale.

I heartily agree with Brickner when he says:

I quite appreciate, and I too have often yielded to, the temptation to perform an extensive osteotomy in these cases of chronic osteomyelitis with sinuses, suppuration and one or more sequestrums. One hopes by chiseling and scraping away to a solid column of so-called healthy bone to eradicate the disease process at once, and to effect a prompt and permanent wound closure. How often such hopes are disappointed! Every chisel stroke, every scrape of the curet is an invitation to fresh sequestrum formation; and the extensive osteotomy often serves to delay rather than to hasten the cure.

MILK INJECTION IN PELVIC INFECTION*

PETER MARSHALL MURRAY, M.D.

NEW YORK

IT IS generally accepted that the use of foreign protein therapy is sound and productive of good results in a great many cases. It is also safe to state that the great majority of workers have adopted sterile cow's milk as the agent of choice. Robert Schmidt of Prague,¹ who introduced the procedure, "selected milk because it was always available even in the remotest village and because its source, the organism of the cow, seemed to him as reliable as any laboratory."

It is our practice on the Second Gynecological Division, Harlem Hospital, Service of Dr. H. C. Falk, to use plain cow's milk from which the top cream has been removed, boiled in a water bath for ten minutes in a sterile test tube. Ordinary ice box milk is used simply because of the item of expense; while satisfactory, it is recognized that the wide possible bacterial variation in certified milk and milk that has been opened and exposed constitutes a real barrier to accurate scientific observation.

The effect on the organism of the injection of sterile milk, as stated by Gellhorn,² Petersen³ and others, may be summed up as "due to plasma activation. All the cells of the organism are stimulated to greater activity none more so than those cells which have been weakened or paralyzed by infection." Leucocytes are increased in number and are more active; there is consequent increased production of antibodies and enzymes. There is also increased tolerance to intoxication and increase in permeability of the capillaries, promoting increased lymph flow and freer exchange between blood plasma and cell content. Clinically, there is usually increased activation in the lesion, evidenced by swelling, some febrile reaction and

increase in tenderness, which soon subsides with prompt improvement of subjective and objective symptoms.

CONTRAINDICATIONS

Pulmonary tuberculosis, alcoholism, various cardiac lesions and diabetes are recognized contraindications. Pregnancy is also listed as a contraindication. We have not used milk injections in any case of pregnancy; therefore, we are unable to record any experience. Petersen³ warns against its use if there is a history of hypersensitiveness, asthma, urticaria, angioneurotic edema. Recognizing this possibility, although Gellhorn² states, "anaphylactic shock need not be feared; only three cases of this kind have been reported in the literature of the world," we have not as yet felt it necessary to inject intradermally a small amount of milk to determine sensitivity.

Reactions varying from slight local tenderness to severe constitutional effects, such as chills, fever and vomiting, are described. In the great majority of cases reactions do not constitute an objection to this method of treatment.

We have observed no cases of abscess formation and no induration or local irritation other than transient in our cases. We should hesitate, however, to use non-sterilized milk, although Duke⁴ "uses pasteurized hospital milk kept in ice-box at temperature of 50°F. This milk is not sterilized but is centrifuged and the milk drawn up into the syringe with the needle well below the cream line." He also states, "in a short series there was no abscess formation and patients experienced only a temporary discomfort or soreness."

In our 22 cases, 14 had no reactions. Three cases were recorded as having

* Read before the Clinical Society of Harlem Hospital, October 31, 1929.

reactions. In one case there was a slight chill after the first injection (this patient had five injections). In 2 cases there was a moderately severe reaction with leg and general body pains after the first injection. In one case the reaction was so severe, with headache, vomiting, joint pains, and malaise coming on about two hours after injections, the milk was discontinued after the third injection. This patient, while she had an increase in temperature and a marked increase in leucocytes, felt distinctly worse. Most observers agree that the mild reactions might possibly be due to the accidental injection of a small amount of milk into a vein. It is also agreed that it is good practice to make sure a vein has not been punctured by withdrawing the piston a trifle before injecting. Surface anesthesia by ethyl chloride spray allays nervous apprehension and is distinctly worthwhile.

Averett⁵ reports "in first six cases violent reactions, severe chills, fever and refusal of patient to continue." Since the general use of fat free milk as suggested by Graves⁶ it is uncommon to find reports of consecutive violent reactions.

EFFECT ON TEMPERATURE

The temperature was recorded before and six hours after injection. As a rule, the temperature showed a rise of from 2° to 3°F., the average being 1.5°. The next day there was a reduction in temperature from 1° to 3°F., showing a net reduction of about 1°. The temperature was normal after two injections in 3 cases; after three injections in 3 cases; after three injections in 4 cases. The average number of injections given was 4.8. In one case the milk was discontinued after five injections, the temperature becoming normal three days after the last injection.

EFFECT ON LEUCOCYTE COUNT

Averett⁵ states: "I have found a leucopenia with a decrease in polynuclear but increase in lymphocytes chiefly the small lymphocytes."

The leucocyte count total and differential was taken immediately before and six hours after injection. There was an increase in the total count of from 2000 to 8000, the average increase being 3000 to 4000. For some reason, in a small percentage of cases there was a decrease in the polymorphonuclear count, amounting to from 4 to 10 per cent. Our experience thus differs from that Averett and conforms to the experience of the majority of workers.

EFFECT ON CLINICAL COURSE

Twelve patients were promptly and distinctly improved. One patient was not benefited; 2 patients did not feel distinct improvement until three days after the injections were discontinued. In the majority of cases clinical improvement was marked after the second and third injections.

No patient was given milk injection until five to seven days of conservative treatment had failed to reduce temperature and afford subjective relief. Upon admission each case of pelvic inflammation is immediately put on conservative treatment: absolute rest in bed, elevation of head of bed, ice bag to abdomen, low simple enema daily or every other day, hot alkaline douches morning and night. This routine is usually sufficient to effect reduction of temperature and marked clinical improvement in five to seven days. The cases in this report failed to respond to this routine; their improvement, in our opinion, was unquestionably due solely to foreign protein therapy. Included in this report are:

| | Cases |
|--------------------------|-------|
| Pelvic cellulitis | 3 |
| Pyosalpinx | 9 |
| Postabortal sepsis | 4 |
| Sepsis with parametritis | 4 |
| Gonorrheal arthritis. | 1 |
| Pelvic peritonitis | 1 |

It seems reasonable, therefore, to conclude:

1. Milk injection is a valuable adjunct

in the conservative treatment of pelvic infection.

2. It is without uncomfortable local or systemic reaction except in a very small percentage of cases.

3. Marked increase in the total leucocyte count and a corresponding increase in the polymorphonuclear is the rule; in 75 per cent of cases the temperature promptly returned to normal after milk injections.

4. Definite clinical improvement was noted in 60 per cent of cases.

SPINAL ANESTHESIA AND SHOCK STRETCHER*

H. DAWSON FURNISS, M.D., F.A.C.S.

NEW YORK

THE stretcher illustrated was suggested by the ill effects caused by the transportation of spinal anesthesia

slots on one of the transverse bars of the stretcher. These slots are so placed that they are adjustable to three widths. The

FIG. 1.

patients from the operating table to their beds on the ordinary stretcher, on which it was impossible to maintain a head low position, so vital in these cases.

The new stretcher provides for this position by being hinged at the head end, and the desired foot elevation obtained by operating a worm gear by means of a handle at the foot end of the stretcher.

Shoulder braces, which prevent the patient from sliding, are slipped into

FIG. 2

lower framework of the stretcher is fitted to hold the braces when not in use.

This stretcher has also been used to great advantage in tonsil and adenoid cases and in cases of shock. For pelvic drainage cases it can be used in the reverse position, and in any case as the ordinary stretcher.

* Submitted for publication November 9, 1929.

those bones. The acetabulum is fractured only when sufficient force is applied to the shaft of the femur just below the

Boorstein¹ reports 6 cases of separation of the symphysis pubis in pregnant women due to difficult labor, the injudicious use

greater trochanter and in line with the long axis of the neck of the femur. Separation of the symphysis pubis (which we consider under the heading of fractures because the symphysis is not a true articulation, but a cartilaginous union of bones) occurs in our series only in connection with other fractures and in severe injuries. In general the same is true of sacroiliac separations.

ETIOLOGY

According to available statistics fractures of the pelvis comprise approximately 2 per cent of all the fractures of the human skeletal system. There is, in our practice, a noticeable increase in their incidence in the last five years. Our experience is that pelvic bones are fractured usually through direct violence or indirect violence. Only a very few result from muscular action. Table II shows that falls were responsible in 11 cases, automobile accidents and crushing injuries in 9 cases each, and various other injuries in 4.

Unique in the literature are 2 cases reported by Steiner⁷ in which spontaneous multiple fractures occurred in the pelvis of men of middle age, who for a number of years had been undernourished and had developed a starvation osteomalacia.

TABLE II
ETIOLOGY OF PELVIC FRACTURES

| Cause of Fracture | Case Number | Total | Per Cent |
|-------------------|---|-------|----------|
| Falls | 5, 8, 11, 14, 16, 18, 21, 23, 25, 32, 33 | 11 | 33 3 |
| Auto accident | 1, 2, 3, 4, 6, 7, 17, 28, 29 | 9 | 27 2 |
| Crushing injury | 9, 10, 15, 20, 22, 26, 27, 30, 31 | 9 | 27 2 |
| Other injuries | 12 Struck by foreign body 13 Jumped from burning bldg. 19 Knocked off truck 24 In falling elevator | 4 | 12 1 |

of forceps and contracted pelvis. We have no experience with the two last-mentioned causes.

CLASSIFICATION

The following classification of pelvic fractures is suitable for the present discussion:

1. Fractures of the pubis. This is the most common variety and makes up 56 per cent of all the fractures in our series (Table III). Out of a total of 33 cases of

fractures of the pelvis 23, or 70 per cent, had fractured one or more rami. Of these, 9 fractured one ramus, 10 two rami, and

called double vertical fracture of Malgaigne (See Fig. 2). This fracture occurred twice in our series.

FIG. 3. Roentgenogram of Case XXV. Fractured acetabulum.

FIG. 4. Roentgenogram of Case XVII. Separation of sacroiliac synchondrosis and of symphysis pubis.

4 four rami of the pubic bone, making a total of 45 fractures of the pubis in a grand total of 80 fractures. Figure 1 illustrates this type of fracture.

TABLE III
SUMMARY OF PELVIC FRACTURES

| Bones Involved | Cases | Total Cases | Total Frac- tures | Per Cent of All Cases | Per Cent of All Frac- tures |
|-----------------------------|---|-------------|----------------------|--------------------------------|---|
| Pubis | | | | | |
| One ramus | 3, 4, 5, 8, 11, 21, 23, 24, 33 | 9 | 9 | 27.2 | |
| Two rami | 1, 7, 9, 10, 13, 16, 18, 22, 27, 29 | 10 | 20 | 30.3 | |
| Three rami | 0 | 0 | 0 | 0 | |
| Four rami | 12, 28, 30, 31 | 4 | 16 | 12.1 | |
| | | 23 | 45 | 69.7 | 56.25 |
| Ischium | | | | | |
| One ramus | 4, 5, 6, 8, 11, 15, 23 | 7 | 7 | 21.2 | |
| Two rami | 7 | 1 | 2 | 3.0 | |
| | | 8 | 9 | 24.2 | 11.2 |
| Ilium | 4, 11, 14, 19, 21, 25, 29, 32 | 8 | 8 | 24.2 | 10.0 |
| Pubic separation | 10, 11, 13, 17, 20, 23, 27 | 7 | 7 | 21.2 | 8.5 |
| Sacrum. | 11, 18, 20, 26, 33 | 5 | 5 | 15.1 | 6.2 |
| Acetabulum | 2, 22, 23, 25 | 4 | 4 | 12.1 | 5.0 |
| Sacroiliac separa- tion. | 3, 17 | 2 | 2 | 6.0 | 2.5 |

3. Fractures involving the acetabulum. This fracture was present in 4 of our patients. It is the type referred to by Sever⁵ as the most disabling of all pelvic fractures, especially when complicated by central dislocation of the head of the femur. (Fig. 3.)

4. Separation of the symphysis pubis or of the sacroiliac articulation. These conditions occurred in association with other fractures usually. In case XVII both of these separations occurred without any other fracture. In our series there were 7 pubic and 2 sacroiliac separations. (See Fig. 4.) The degree of separation may vary from an almost imperceptible distance to several inches.

5. Fractures of the sacrum or of the ischium. These occur in severe injuries and usually accompany other fractures of the pelvis. The ischium was fractured in 8 patients, one of whom had both sides involved, while the sacrum was broken 5 times. Only one such fracture was uncomplicated by other fractures. Two of the sacral fractures were due to falls on the buttocks and both developed postsacral hematomas, one of which was estimated to contain as much as 500 c.c. of blood. The question of shortening the con-

2. Fractures of the pubis with fracture of the ilium just posterior to the acetabular cavity or near the sacroiliac joint, the so-

valescence by aspiration came up but was rejected because of the danger of secondary infection. Both hematomas slowly ab-

which adds gravity to an already serious condition.

2. Pain is usually complained of by the

FIG. 5. Roentgenogram of Case XVIII. Fractured sacrum.

FIG. 6. Roentgenogram of Case XIX. Isolated fracture of ilium.

sorbed spontaneously, leaving no trace behind. (Fig. 5.)

6. Isolated fractures of the ilium. This type occurred eight times in our series and is thus not uncommon. It is not of great importance because usually the pelvic girdle is left intact. (Fig. 6.)

Fractures of the pelvis may be complete or incomplete. Most often a complete fracture is accompanied by considerable displacement and overriding of the fragments. This is especially true in the fracture of Malgaigne and in other double vertical fractures. When all four of the pubic bones are broken through there is formed a disconnected fragment lying anteriorly, often markedly displaced. Extensive splintering of the bones is quite common and often accompanied by penetration of the soft tissues by the splinters. Tears occur which involve the pelvic viscera. No instance of compound fracture of the pelvis has come to our notice.

DIAGNOSIS

The diagnosis of pelvic fracture is often overlooked, especially when other fractures have taken place concomitantly. It can usually be made on the following points:

1. There is a history of a severe injury, followed in many cases by profound shock

patient. It can also be elicited by compressing the iliac crests, by flexing the thigh on the abdomen, or by backward pressure on the anterior superior iliac spines when the patient is in the recumbent position.

3. Loss of function is especially marked if the fracture is at all extensive. There is great difficulty in standing and walking.

4. The signs of local trauma vary with the location and the extent of the fracture. Ecchymosis and discoloration in the perineum should lead one to suspect fracture of the pubis. Similar signs over the buttocks should lead one to careful examination of the sacrum.

5. Crepitus is easily elicited, especially where the ilium or the pubis is involved. This method of investigation must, however, be indulged in sparingly.

6. Deformity is sometimes discernible with difficulty, especially in thickset patients. In spare persons marked asymmetry may be detected at a glance. This is especially easy when the pubic bones are fractured, or when there is a separation of the symphysis pubis. In central fracture dislocation of the acetabulum with inward displacement of the head of the femur through the acetabulum a decided lessening of the trochanteric prominence is evident.

On rectal or vaginal examination the head of the femur may be revealed in the true pelvis.

7. Measurements. These usually confirm the appearance of the asymmetry or deformity; the most reliable measurements being those from the umbilicus to the anterior superior iliac spines.

8. Preternatural mobility can often be elicited by grasping the anterior superior spines in the palms of the hands and exerting pressure directly backwards. In many cases grasping one leg and moving it with an alternate pushing and pulling motion will reveal movement of the fractured parts.

9. A vaginal or rectal examination should both be made where any doubt exists as to the possibility of isolated fractures of the sacrum, coccyx, or ischium. The method of Lewin³ is to insert the index finger into the rectum and palpate the coccyx and the sacrum between that finger and the thumb. Abnormal mobility and crepitus are easily detected. Thus is furnished also sometimes the first evidence of severe injury to the pelvic organs.

10. A roentgenological examination is of paramount importance in all cases, for a considerable number of the fractures of the pelvis escape recognition otherwise until sometime following the injury. The symptoms may be masked by shock, or the surgeon's attention may be drawn to other simultaneously produced injuries, such as fractured ribs or vertebrae. It is very significant from the medico-legal aspect that one get visual demonstration of the pelvic bones to establish evidence as to possible fractures. It is a curious fact that the absorption of bone along a linear fracture will often serve to increase the contrast in a picture taken two or three weeks after the injury and to make the line of fracture easy of demonstration. For that reason it may become necessary, in doubtful cases, to take a second radiogram about three weeks after the injury. One should not forget in examining x-ray films that occult spina bifida and other

congenital deformities are comparatively common conditions, and should, therefore, be recorded at the first examination, because such abnormalities serve as a basis for unfair claims by unscrupulous damage-seeking litigators.

TREATMENT

The transportation and movement of patients with fractures of the pelvis must be done with the greatest care, both on account of the shock already present and for fear of producing or increasing visceral injury. In all instances the patient should be transported in an ambulance to a hospital after first aid has been given in the form of a wide moderately firm bandage around the pelvis to immobilize it. The knees may likewise be tied together to steady the broken parts.

After the patient is placed flat in bed shock demands the first consideration, and a complete physical examination is made at once.

If there is bleeding from the urethra or from the rectum the source of such hemorrhage is established at once. The patient is warned against passing the urine for fear of pelvic extravasation. It has been our practice to pass a sterile soft rubber catheter at once in order to avoid this, and if blood comes from the urethra the catheter is fixed in place. Failing to pass a catheter usually implies serious laceration of the urethra and suitable operative treatment is demanded.

It is rarely necessary to make elaborate attempts at reduction of the fractured fragments, for, as a rule, they tend to reduce themselves after the patient is placed flat on his back. Where there is an upward displacement of the acetabulum on one side extension should be applied in order to avoid shortening. We use only enough weight to counterbalance the muscular pull, as this is enough to cause a gradual replacement of the fragments to a more or less normal position. In women of the childbearing age the potential complication of narrowing of the pelvic

outlet must be kept in mind and an attempt made at proper reduction. Overriding of fragments of the pubis can

about nor work away from their proper locations. The legs are now abducted far enough to form an angle of about

FIG. 7. Fronto-distal view of plaster-of-Paris case applied for fracture of pelvis.

FIG. 8. Anterolateral view of plaster-of-Paris case applied for fracture of pelvis. Pictures taken about four weeks after application.

often be easily corrected by simple manipulation with one or two fingers in the rectum or vagina.

The essential principle to be kept in mind in the treatment is immobilization. This was secured in Westerborn's⁸ cases by bed rest with or without a girdle or sling. We have found plaster-of-Paris cases of the body extending from the umbilicus to the middle of the thighs the most satisfactory method. They are especially comfortable and give complete safety to the patient who must be turned and lifted for baths and other toilet necessities. Our practice is to wait from one to several days for the patient to overcome his shock and to secure reposition of the fragments by extension and traction. After that he is placed on a fracture table and supported on the sacral saddle. Next to the skin is placed the usual stockinet and this covered by a well-applied dressing of several layers of cotton wadding, fastened down by a turn or two of gauze bandage. Felt pads are next placed over the bony prominences of the sacrum, the iliac crests and spines, and the trochanters. These felt pads are fixed in place by the first few turns of plaster-of-Paris bandages, so that they will not slide

30° with each other, and the plaster-of-Paris is applied. A cross-bar is fixed between the thighs to facilitate handling and turning of the patient in his bed. Figures 7 and 8 show the appearance of such a case when finished and dried. In some patients it may be necessary to leave the extension on the leg and apply the plaster case over it, later resuming the traction. Where the symphysis is widely separated, or where the sacrum is fractured, it is well to put on the case with the patient suspended in a sling rather than to make use of the sacral rest on the fracture table. No anesthetic is required for application of a plaster case. After four to six weeks the case is removed, but the patient is kept in bed for several weeks more in the severer cases. The actual stay in the hospital varies greatly according to the extent of the fracture, and also according to the type of personal care demanded by the patient. In our series the smallest number of days spent in the hospital after the injury is one, the greatest 112, the average 43 (See Table 1).

In those cases where multiple incisions of the perineum or a suprapubic cystotomy may become necessary we place the patient

on a simple rectangular frame over which two sheets of canvas are tightly stretched, so as to leave a 7 inch gap between them running across the middle of the frame. When the patient's buttocks are placed into this gap the pelvis is given more or less fixation, which can be easily augmented by a tight band from side to side of the frame over the top of the symphysis. Such a frame is very satisfactory also from the point of view of sanitation and the care of urinary drainage.

There are few, if any, indications for open reduction of fractures of the pelvis. Wiring and suturing of the symphysis pubis have been recommended, but we have not had occasion to do this. Fracture of the coccyx may be followed by continued pain. In those cases the bone should be removed.

For central fracture dislocation of the head of the femur and acetabulum we consider the method of Whitman⁹ the procedure of choice. Fixation of the pelvis is secured by full abduction of the intact leg, after which sufficient abduction of the involved leg will stem the trochanter against the upper acetabular border and rotate the head of the femur down and out into its normal position. The usual case is applied for immobilization and also moderate traction to overcome the muscle pull. This method is also advocated by Eliason and Wright² who report a series of 15 cases, some of which were of severer degree of deformity than any of ours. The method of skeletal traction used by Putti,⁴ who drives a steel pin through the trochanter, we think is too elaborate and opens avenues for infection of the bones. We have not experimented with it.

COMPLICATIONS

In our experience the most common complication of fracture of the pelvis is rupture of the pelvic viscera. In 7 cases, or 21 per cent, there was laceration of the urethra, rupture of the bladder, or tearing of the rectum, with subsequent fistula formation in 2, or 6 per cent. Both of these

we demonstrated definitely by the injection of dye solutions, and, what is more interesting, both eventually closed spontaneously. The visceral injuries accompanying pelvic fracture form the material for another paper and will not be discussed further here. (See Table iv.)

TABLE IV
COMPLICATIONS OF PELVIC FRACTURES

| Case | Complication | Treatment | Result |
|------|--|--------------------------|--|
| 7 | Ruptured urethra Ruptured bladder | Operation | Rectovesical fistula |
| 9 | Ruptured urethra Osteomyelitis of the pubis | Operation | Perineal urinary sinus and 75 per cent incapacitated |
| 10 | Ruptured urethra | Indwelling catheter | Complete recovery |
| 16 | Ruptured urethra bony spicule pierced bladder | Indwelling catheter | Complete recovery |
| 18 | Sacral hematoma | Rest | Complete recovery |
| 20 | Ruptured urethra | External urethrotomy | Complete recovery |
| 23 | Fract. vertebra | Rest | Complete recovery |
| 25 | Fractures of 6 vertebrae 6 ribs | Rib resection | Empyema |
| 26 | Sacral hematoma | Rest | Complete recovery |
| *29 | Cerebral hemorrh. | | *Death |
| 31 | Ruptured urethra Ruptured rectum | Operation, trans-fusion | Satisfactory recovery |
| 32 | Fractures of clavicle and one rib | Rest, splint | Complete recovery |
| 33 | Ruptured urethra Fractures of three ribs | Indwelling catheter rest | Convalescent |

* Complication not due to pelvic fracture.

Concomitant fractures elsewhere in the body were present four times (12 per cent) and became a very serious factor in one instance. Case xxv fractured a number of transverse vertebral processes and six ribs on one side. A hemothorax developed and later an empyema, which had to be drained by rib-resection. The patient, eighteen months after the injury, is still incapacitated, not from the pelvic fracture but from the complicating fractures of the ribs. Case xxxiii had three fractured ribs, and cases xxiii and xxxii a fractured lumbar vertebra and clavicle, respectively. All proceeded to uneventful recovery. Westerborn⁸ states that these two complications are the most common in his

series, 30 per cent being complicated by other fractures and 16 per cent by rupture of a pelvic viscus.

Postsacral hematoma was present in cases XVIII and XXVI. Both absorbed spontaneously without special treatment.

Osteomyelitis of the pubis occurred in one case following extravasation of urine. A perineal urinary sinus existed for several months but eventually closed spontaneously.

Case XXIX was an old man with generalized atherosclerosis in an advanced degree. He died of a cerebral hemorrhage (substantiated at autopsy) a few days after leaving his bed. It is probably safe to state that this condition was not a true complication of his pelvic fractures.

Two complications with which we have no experience are fat embolism and injury of the sacral plexus.

PROGNOSIS

We find that uncomplicated and properly treated pelvic fractures proceed to complete recovery in the vast majority of cases. A protracted convalescence or permanent disability are usually due to complications. Westerborn⁸ reports that 93 per cent are restored without marked incapacity. In our experience 85 per cent are free from disability, while 15 per cent are more or less permanently incapacitated. The ultimate results in 5 of our cases are not known to us. We have reason to believe, however, that they are entirely satisfactory, since the extent of their injuries was of the less serious nature and no complications were present in any of them.

A word of explanation is probably necessary here. It is our custom to regard a patient as free from permanent disability if he is able to return to his former occupation or one similar in nature. Thus it becomes obvious that a patient completely restored functionally may show some slight anatomical changes which we have here disregarded. Ability to perform his usual daily work is the criterion of our

results. This seems to us the fairest basis upon which to estimate the final consequences, since all but 5 of our patients are workers active in some industrial occupation.

A few outstanding points of the material here presented are of interest. (Tables I and III.) The ages range from 16 to 72 years; average age being 40 years. There are 6 females and 27 males. The left side alone is involved 13 times (39 per cent); the right 10 (30 per cent); both sides 10 times (30 per cent). The smallest number of fractures in one patient is 1; the greatest 5; the average 2.42. The total number of fractures in all 33 cases (not including complicating fractures) is 80. Eight patients have a single fracture (24 per cent); 11 have 2 (33 per cent); 7 have 3 (21 per cent); 6 have 4 (18 per cent); and 1 has 5 fractures (3 per cent). The greatest number of days of treatment before final discharge is 305; the least 35; the average 95 days.

SUMMARY AND CONCLUSIONS

1. Pelvic fractures are the result of severe injuries, most common of which are falls automobile accidents, and crushing injuries.

2. There is a gradual increase in the incidence of pelvic fractures in the last few years.

3. The most common site of fracture is the pubis.

4. Conservative treatment should be in order unless definite operative indications present themselves.

5. Injuries of the urethra and bladder are the most common complications.

6. The most serious factors are not the fractures *per se* but the visceral complications.

7. Surgical shock usually accompanies fractures of the pelvis and should receive immediate and primary consideration.

8. Taken as a whole fractures of the pelvis offer a very favorable prognosis both as to life and as to function.

CYSTINE CALCULI

REPORT OF THREE CASES*

ROY B. HENLINE, M.D., F.A.C.S.

NEW YORK

TREATMENT of urinary calculi is always a tedious and difficult surgical problem because of the possibility of recurrence. The treatment of a patient with cystine stones is both medical and surgical, and even after resorting to every known remedy, we often find that we have failed. The greatest problem is not in the surgical removal of the stones, but in preventing their reformation which results in damage of the kidneys and impairment of renal function.

HISTORY

In 1810 Wollasten⁵⁵ read a paper before the Royal Society of London "On cystic oxide, a new species of urinary calculus." He described two stones, one of which had been removed in 1805 from a boy five years of age and the other from a man of thirty-six. He called them cystic oxide since both had been removed from the bladder. Berzelius³⁰ in 1822 proposed the name cystine because the substance was found to be not an oxide. The first observations on patients were made by William Prout⁴⁰ in 1821 who described one with cystinuria and one with a cystine bladder stone. Lassaigne²² in 1823 found a cystine stone in the bladder of a dog. Baudrimont and Malagutti³⁰ in 1837 discovered that cystine contained sulphur but Thaulow⁴⁷ in 1838 was the first to determine the correct chemical formula.

As early as 1840 William Prout⁴⁰ states that the cystic oxide disease is of an hereditary character and occurs in members of the same family. He also points out that the peculiar composition of cystic oxide shows that its formation results from an imperfect assimilation of the albuminous principle and seems to be a peculiar form of hepatic disease. Strangely

enough this corresponds very closely to our modern conception of the disease. Dewar and Gamgee¹³ in 1901 discovered cystine in the sweat. Drechsel and Cloetta⁹ found cystine in the liver of a horse and in the kidney of an ox. Spiegel¹⁸ in 1901 proved that cystine was an intermediary product of protein metabolism. Cystine was produced from horn and hair synthetically by Embden,¹⁶ and by the hydrolysis of keratine by Morner.³⁶

Udranszky and Baumann⁴⁹ in 1889 believed there was some connection between cystine diseases and intestinal putrefaction. Another theory of the origin of cystine in the urine brought forth by Stadthagen and Brieger⁴⁵ says that it is caused by an intestinal mycosis because of the presence of certain diamines in the urine and feces of cystinurics.

In 1856 Thoel⁴⁸ showed the familial occurrence of cystine by finding it in several members of the same family. Charles A. Simon¹⁸ in 1900 collected from literature 103 cases of cystine stones.

DESCRIPTION

Cystine chemically is a very complicated organic compound. It belongs to the group of amino-acids, being the only one which contains sulphur. Its sulphur content is about 25 per cent.

Cystine is absolutely necessary for the growth of the body. Feeding experiments on rats and dogs have shown that cystine is an essential amino-acid and hence necessary in the diet if growth and maintenance of body weight is desired. Cystine and cysteine cannot be synthesized in the body.³⁸ Some cystine, however, is stored in the muscles and is called endogenous cystine, in contradistinction to the exogenous cystine which is utilized directly

* Read before the Section of Genito-Urinary Surgery, New York Academy of Medicine, May 15, 1929.

from the food protein. Lewis and Lough²⁴ believe that the ingested cystine is properly assimilated and utilized by the body and

of cystine. The Chinese edible birds' nests, which are formed by the mucin-like salivary secretion of these birds, contain the

FIG. 1.

FIG. 2.

that cystinuria is the result of improper catabolism and thus almost entirely endogenous in origin. They failed to find any appreciable difference in the excretion of cystine on a high or low protein diet even when cystine itself was added. An experiment by Robson⁴¹ showed that the average cystine excretion on a high and low protein diet varied from 1.1 gm. to 0.71 gm., and concludes that the cystine excretion is in almost direct ratio to the protein in the diet. Further experiments have shown that neither cysteinic acid, taurine, or any other substance is capable of replacing cystine.²³

Since cystine is an indispensable essential amino-acid and growth is limited by a low cystine diet, we would expect a high cystine content in food which is most important for infant feeding. Thus the lactalbumin of milk contains 4.5 per cent

greatest amount of cystine.⁵² All proteins contain some cystine but the amount varies considerably. Milk, nuts, beans, whole wheat bread, rye, eggs, oats and meat contain much cystine, while corn, gelatin, cheese, lentils, peas, cow-peas, and red kidney beans contain much smaller amounts.⁵⁶ Fish contains less cystine than any other meat.

It was formerly believed that normal urine contained no cystine. According to investigations by Looney,⁵⁷ slight traces may be found in normal urine averaging about 4 mg. in 100 c.c. of urine. This corresponds approximately to one-third the amount one finds in the urine of a cystinuric. Cystine crystals, however, are not found in normal urine but only appear after this limit is exceeded.

Cystine occurs in cystinuria as hexagonal, colorless, highly refractive crystals, occa-

sionally in the form of needles. Cystine stones are of a honey-yellow, waxy appearance. They have a somewhat crystallized appearance and a peculiar semitransparent luster. They may be very small or large enough to completely fill the kidney pelvis. These stones may be purely cystine but are often mixed with other salts. Pure cystine stones have no distinct laminae, but appear as a mass confusedly crystallized.

There are three methods of determining the amount of cystine: (1) gravimetric (Gaskell¹⁷); (2) polarimetric (Magnus-Levy³³); and (3) colorimetric (Looney⁵⁷). Cystine is readily soluble in alkalis but not in alcohol, acids or water. It decomposes readily in the urine.

F. W. Wards in 1923 published some very interesting experiments in which he shows that cystine is the only amino-acid that has any marked absorption of ultra-violet light. He says:

It would appear suggestive that the presence of cystine in hair and wool (where the concentration approaches 10 per cent) is of physiological importance in the protection of the organism against the harmful effects of prolonged exposure to sunlight. The curious custom of the Arabs in wearing heavy but loosely fitting woolen clothes has apparently a strong justification in the protective effect of the cystine present in the wool.

CHEMISTRY

The chemical formula of cystine according to Friedman and Neuberg³⁰ is:

By oxidation this is split into two molecules of cysteinic acid. These products of cystine are stored in the blood cells, liver, and tissues, and hold the oxygen in various parts of the body for use. Hence they regulate the equilibrium between the oxidants and reductants of the cells.

Cystine and tyrosine have been isolated from hydrolyzed crystalline insulin, proving the presence of these amino-acids in

FIG. 3.

the "insulin molecule."⁵¹ Cystine is a derivative of insulin in which cystine is probably linked to the rest of the molecule by a peptide linkage.

TOXICITY

The toxic action of large doses of cystine has experimentally been proved by many workers. Lignac²⁸ in 1925 found severe tubular injury of the kidneys in mice from the subcutaneous injection of a suspension of cystine. H. B. Lewis²⁶ in 1925 fed cystine to rabbits and produced similar injuries to the kidneys. Curtis and Newburgh⁵⁸ in 1927 reached the following conclusions from experiments on white rats: (1) An 8 per cent casein diet does not contain sufficient cystine to permit good growth. (2) The basic diet of 18 per cent casein contains sufficient cystine for growth. (3) Cystine in the diet becomes harmful when it contains roughly two and a half

times the requirement and with increasing amounts of cystine the injurious effects become more and more severe. A 5 per cent

other respect. Many individuals who excrete large amounts of cystine go through life with out any difficulties, and it is only

FIG. 4.

FIG. 5.

addition of cystine works as a powerful poison and 10 per cent kills the rats in a few days, causing a diffuse hemorrhagic necrosis of the renal parenchyma.

Cystine also exerts a toxic action on the liver when large doses are administered. A complete necrosis of the liver is caused in four days by adding 20 per cent cystine to the diet.

Cystine apparently exerts no toxic effect in cystinuric patients except rarely in very young children where metabolic disorders are extremely severe. Abderhalden¹ and Lignac²⁹ have reported autopsies on four children who died from inanition in which cystine was found in most of the internal organs. The body requires, or can use, a certain amount of cystine and only a portion of the cystine from the ingested protein is excreted as such, the remainder being used by the body in the normal manner. The metabolism of cystinuric patients apparently suffers no other abnormality. They are usually well developed and entirely normal in every

when calculi are formed in the urinary tract that symptoms occur. Watson and Cunningham⁴⁶ report 1 stone-forming patient in 32 cystinurics, Morris³⁷ 2 in 77 cystinurics, and Sir Henry Thompson reports 3 in 114 patients excreting cystine. Thus only 2.5 per cent of cystinuria cases form stones. About 70 per cent of the reported cases are in males.

Alsberg and Folin³ have proved that the amount of cystine excreted in the urine in a case of cystinuria varied directly with the amount of protein consumed. From 30 to 50 gm. of protein per day is the minimum for normal metabolism, and this amount causes considerable cystine excretion.

SYMPTOMS

It is an interesting feature of cystinurics that they often reveal a history of passing stones sometimes for many decades with only slight transient symptoms. Usually the first symptom noted is renal colic with or without the passage of a stone with hematuria. General malaise or a feeling of

weight in the loins is not uncommon. An attack of renal colic may last from fifteen minutes to two or three weeks. Cystine crystals are usually found in the urine although cystine stones have been removed from the kidneys of patients whose urine never showed cystine crystals. MacAlpine³² noted that the urine of cystinurics on decomposition had a foul odor, probably due to the sulphuretted hydrogen produced during the decomposition of cystine. A silver coin in the pocket of a cystinuric may turn black from the sulphur of the cystine present in the sweat.¹³

Cystine diathesis is an hereditary metabolic error. The youngest cystinuric reported was a baby of ten and one-half months and the oldest a man of eighty-one years.³⁰ This latter patient had never had alarming symptoms although he had passed stones for over thirty years. Cystinuria may be transitory or it may persist throughout life. It often occurs in many members of the same family. Poland, Stras-ser, Morner,³⁶ Cohn,¹⁰ Pfeifer,³⁹ Marcet, Civiale, Thoenel,⁴⁸ Golding-Bird, Hatuier, Ebstein,¹⁴ Lichtenstein,²⁷ Kretschmer²¹ and others have all reported more than one case in the same family.³⁰

Cystine stones may be located anywhere along the urogenital system: urethra, prostate gland, bladder, ureter, kidney pelvis, or renal parenchyma. Nothing can be said of the frequency of their location, as only recently with the development of cystoscopic and x-ray examinations has it been possible to locate them accurately. They are more liable to be multiple than single. Schottmueller⁴³ and Edwards¹⁵ have reported cases with more than one hundred stones.

Cystine has also been found outside the urinary tract. Mueller²¹ reported cystine in the blood in a stubborn case of urticaria; Umber and Burger,⁵⁰ in the muscle; Sherer, in the liver; and in the mesentery and other internal organs by Abderhalden¹ and Lignac.²⁹ Cystine may occur in the urine in phosphorous poisoning, tuberculosis or syphilis.

There is considerable difference of opinion regarding the x-ray shadows cast by cystine stones. Kuemmell⁶ states very

FIG. 6.

definitely that cystine stones do not throw an x-ray shadow. In a case reported by E. Beer⁶ the x-ray showed the large stones but not the smaller ones. Graves says that cystine stones should not cast an x-ray shadow while Thomson-Walker⁴⁶ state that cystine and xanthine give shadows almost as dense as calcium phosphate. Mueller and Stallman reported cases which cast good shadows with the x-ray. Morris³⁷ states that many cystine calculi contain calcium phosphate or magnesium and ammonium phosphate, but that cystine contains from 25 per cent to 75 per cent sulphur and therefore should cast a very deep shadow. Winsbury White⁵⁴ states that cystine and xanthine give poor shadows when in the pure state but of slightly more opacity than those of urates, uric acid, and triple phosphates, because of the sulphur they contain.

TREATMENT

The oldest and still the most modern treatment of cystine calculi is the internal administration of alkalis. Both Cantani⁸

in 1881 and then Beale⁵ (in 1884) advised large doses of ammonium carbonate and successfully treated their patients in this

similar chemical compounds failed completely.

Edwards¹⁵ advises the use of choleic

FIG. 7.

FIG. 8.

manner. In 1914 Jacobi and Klemperer¹⁹ strongly recommended the alkalinization of the urine with 10 gm. of sodium bicarbonate.

Looney found that the neutral sulphur in the urine remained unchanged regardless of the amount of alkalis given and therefore believes that the cystine was merely in solution and not actually decreased in amount. Smillie⁴⁴ demonstrated a decrease in the sediment in an alkaline urine but not in the amount of cystine excreted.

Crowell¹¹ in 1924 described a case where he succeeded in disintegrating kidney stones and keeping the urine free from cystine by the internal administration of alkalis.

Klemperer¹⁹ and Smillie⁴⁴ advocated about the same treatment which consists in the oral administration of 6-10 gm. of sodium bicarbonate daily and a low protein diet. Every attempt to eliminate cystine from the diet by adding very

acid on the hypothesis that endogenous cystine is excreted because of the lack of choleic acid with which it should normally conjugate to become the taurine of the bile salts. This has proved of no benefit. He also suggests intestinal and urinary antiseptics to allay the pelvic infection which furnishes the irreversible colloid that glues the crystals into calculi. Vaccines have been of no benefit.

DIAGNOSIS

The diagnosis of cystinuria is made by finding cystine crystals in the urine. If a stone is discovered along the urinary tract and no cystine crystals are present in the urine, a diagnosis of cystine calculi cannot be made until the stone is removed. The appearance of cystine stones is characteristic. The history of repeated passing of stones is suspicious of cystine calculi.

CASE REPORTS

The following reports concern three

cases presenting cystinuria and cystine calculi:

CASE 1. D. E., a man, aged twenty-nine, was admitted to the Brady Urological Foundation of the New York Hospital February 28, 1927 with a right kidney stone. He complained of pain in the back, hematuria, frequent and urgent urination, and passing of small stones for the past ten years. One brother had previously been operated upon for a cystine stone in the bladder. The remainder of the family had no cystine in their urine and no history of stones. He had been perfectly well and robust with no previous illnesses except that his appendix has been removed ten years previously as a result of the first renal attack. He had passed about 50 small stones which were all soft and easily powdered when dry. A renal colic began with a feeling of depression, followed by hematuria and pain in either the right or left back lasting from four days to seven weeks and ending by the passage of small stones.

Physical examination was entirely normal except for slight tenderness in both right and left costovertebral angles. Urine analysis showed a trace of albumin, sp. gr. 1.021, with blood, pus, and cystine crystals. Blood chemistry:

| | |
|------------------------|---|
| Coagulation time | 4 min. |
| Urea nitrogen | 14 mg. per 100 c.c. of blood |
| Blood sugar | 0.118 per cent |
| Plasma combining power | (CO ₂ tension) 65 vols. per cent |

Previous cystoscopy on February 9 revealed a normal bladder and ureters through which No. 6 F. x-ray catheters passed to the kidneys without difficulty. Kidney function revealed:

| | Rt. | Left |
|-----------------|--------------------------|---------------------------|
| Urea | $\frac{4}{5}$ gm. per l. | $5\frac{3}{5}$ gm. per l. |
| P.S.P. . . | App. 6 min. | 3 min. |
| Per cent 10 min | 2 per cent | 13 per cent |
| Microscopic | 8 w.b.c. per field | Blood |
| Cultures | Sterile | Sterile |

X-ray showed large right and left kidneys in good position with a stone the size of the end of one's thumb in the right kidney pelvis. (Figs. 1 and 2.) A pyelotomy was done March 1, no sutures being used in the kidney pelvis. Recovery was uneventful.

The stone was oval and flattened, measuring $9.5 \times 15 \times 21$ mm. It was rather hard in

consistency and when broken it was seen to be made up of light brown translucent large "granules," composed of cystine.

FIG 9.

He was next seen June 25, 1927 when his right ureter was dilated. On February 23, 1928, he suffered an attack of right renal colic at which time his right ureter was dilated and a large group of cystine crystals were crushed in the bladder. On March 5, 1928, he had pain in his left flank and was unable to void. Catheterization of his bladder released no urine. The left ureter was dilated with a No. 8 F. catheter which released a continuous flow of urine for five minutes. The right ureter was dilated with No. 9 F. bougie on May 12, 1928, June 2, 1928, and June 16, 1928. He was not seen again until February 2, 1929 when he complained of pain in his left kidney region. At this time an attempt to pass a No. 9 F. bougie met an obstruction just below the left renal pelvis. On February 13, 1929, he suffered severe pain, but passed no stone and his urine showed no blood. An attempt to dilate the left ureter encountered an obstruction just above the ureteral orifice and another about half way up the ureter which could not be passed. An x-ray showed the right kidney pelvis almost completely filled with stones. (Fig. 3.) There was a questionable

shadow in the region of the left kidney pelvis, but none could be seen along the course of the ureter. Two small stones were passed on

Foundation of the New York Hospital November 22, 1928 with bilateral kidney stones.

She complained of pain in the right side

FIG. 10.

FIG. 11.

February 20, 1929 and one large one on April 27. On May 7, 1929 his urine showed a few W.B.C., rare R.B.C., few cystine, and many calcium oxalate crystals. He had taken various amounts of alkalis by mouth but has only been cooperative when in severe pain or urinary retention.

Cystoscopy May 10, 1929 revealed a slightly congested bladder. A No. 7 F. catheter passed to the right kidney easily but it was impossible to pass any catheter up the left ureter. A No. 6 F. bougie passed with difficulty almost to the left kidney. Kidney function showed:

| | Rt. | Left |
|-------------------|----------------------|----------------------|
| Urea. | 5 mg. per l. | 0.2 mg. per l. |
| P.S.P. | app. 5 min. | ? |
| Per cent 10 min.. | 6.5 per cent | 2 per cent |
| Microscopic | 18 W.B.C. per H.P.F. | 11 W.B.C. per H.P.F. |
| Cultures | Negative | Negative |

X-rays on this date showed that the stones in the right kidney pelvis were somewhat larger in size.

CASE 11. E. P., a woman, aged thirty-seven, was admitted to the Brady Urological

and pit of her stomach with occasional attacks of renal colic accompanied by nausea and frequency of urination for a number of years. Her family history was irrelevant. During one of these attacks fourteen years ago her appendix was removed. Stones had been removed from both the right and left kidneys five years ago. She was comfortable for almost a year after these operations.

Physical examination revealed a well-nourished, apparently healthy woman with slight tenderness in the right costovertebral angle.

Urine analysis showed a trace of albumin, sp. gr. 1.012, with blood and pus.

Blood chemistry:

| | |
|------------------------|---|
| Urea nitrogen | 11 mg. per 100 c.c. blood |
| Blood sugar | 0.107 per cent |
| Plasma combining power | (CO ₂ tension) 58 vols. per cent |

November 22, 1928 Intramuscular P.S.P. 3 per cent—8 per cent—8 per cent—7 per cent—8 per cent. (Half hour specimens.)

Previous cystoscopy on November 1, 1928 revealed slight edema around the ureteral

orifices. No. 6 F. catheters passed easily to each kidney.

Kidney function:

| | Rt. | Left |
|---------------------|-------------------------|------------------|
| Urea..... | 13 gm. per l. | 8 gm. per l. |
| P.S.P..... | app. 9 min. | 9 min. |
| Per cent 10 min.... | 2.5 per cent | 2 per cent |
| Microscopic..... | pus 28 per H.P.F. | pus 2 per H.P.F. |
| Cultures..... | staphylococcus albus | sterile |

X-ray plates showed large kidneys with many stones in each pelvis. It was deemed advisable to operate on the right side first because of pain and discomfort. (Fig. 7.)

A right nephrotomy was done November 23 with the removal of one large stone and several small ones. Recovery was uneventful.

Before the patient was discharged from the hospital an x-ray showed the complete absence of stones in her right kidney. (Fig. 8.) She was instructed to take 40 grains of sodium bicarbonate three times daily and to test her urine with litmus paper night and morning to be certain it remained alkaline. She was also advised to maintain a low protein diet and to return every two weeks to have her kidney pelvis lavaged. She has carried out none of these instructions and in all probability will form other stones in her right kidney.

CASE. III. S. H., a boy, aged sixteen, was first admitted to the New York Hospital on November 1, 1917 with pain in the right lower quadrant. This pain began one and one-half years previously with severe cramps which recurred at intervals. There was some tenderness over McBurney's point. His urine contained a few w.b.c. His appendix was removed.

On February 20, 1922 he was readmitted with pain in the left groin, having been awakened at night by a severe stabbing pain. He had some frequency of urination and an occasional w.b.c. in the urine. Cystoscopy revealed a colon bacillus pyelitis but x-rays and pyelograms showed no stones. Cystoscopy on February 25, 1924 revealed a calculus in the left kidney pelvis which was only apparent because of a filling defect in the pyelogram.

On admission February 25, 1924 he complained of recurrent attacks of renal colic and a heavy sensation in the kidney region with radiating pains to the penis.

Cystoscopy on this date revealed a patchy cystitis with some pus in the bladder. Catheters No. 6 F. passed to each kidney without difficulty. Kidney function:

| | Rt. | Left |
|----------------------|---------------------|--------------|
| Urea..... | 4 gm. per l. | 3 gm. per l. |
| P.S.P..... | app. 4 min. | no app. |
| Per cent 10 min.... | 6 per cent | none |
| Microscopic..... | occ. w.b.c. | many w.b.c. |
| Blood urea nitrogen. | 22 mg. per 100 c.c. | |

Urine analysis showed a trace of albumin with much pus, occasional R.B.C., and cystine crystals.

On March 7, 1924 a left kidney stone was removed through a posterior pyelotomy incision. Small fragments of stone passed out through the wound during convalescence which was prolonged. Dilatation of the left ureter and a retention catheter to the kidney pelvis aided in healing the wound.

On March 28, 1924 a right pyelogram revealed a filling defect opposite the transverse process of the fourth lumbar vertebra. The patient received no further treatment until he was again admitted April 30, 1929. After he was discharged from the hospital in March, 1924, he had considerable pain in his right kidney region. In February 1925, a plain x-ray showed a large stone in the right kidney pelvis. For the next two years he had intermittent attacks of pain in both kidneys, but for the last two years he has had no pain except a feeling of weight in both loins. His only other symptom on admission was frequency of urination every hour. There has been no change in his weight.

Cystoscopy on April 30, 1929, showed a slight congestion of the bladder. No. 6 F. catheters passed to each kidney. Kidney function:

| | Rt. | Left |
|---------------------|----------------|-----------------------|
| Urea..... | 10 gm. per l. | 8½ gm. per l. |
| P.S.P..... | app. 13½ min. | app. 3½ min. |
| Per cent 10 min.... | none | 3½ per cent |
| Microscopic pus.... | 200 per H.P.F. | pus 200 per H.P.F. |

Urine analysis showed a trace of albumin, sp. gr. 1.015 and much pus.

Blood chemistry: May 2, 1929: Urea nitrogen, 24 mg. per 100 c.c. Blood sugar, 0.113 per cent. May 6, 1929: Urea nitrogen, 19 mg. per 100 c.c. May 8, 1929: Urea nitrogen, 13 mg. per 100 c.c.

Plasma combining power (CO₂ tension) 59 vols. per cent.

X-rays taken April 30, 1929 showed multiple calculi in both kidneys as shown in the accompanying pictures. (Figs. 10 and 11.)

Confronted with such a difficult problem it was deemed advisable to do no surgery until we had attempted to dissolve the stones, or to prevent them from becoming larger.

If we could prevent the stones from increasing in size, we might then expect to keep the kidneys from forming new stones, providing

opened pain in both kidney regions and showed symptoms of alkalosis. All medication was stopped and the symptoms gradually subsided.

FIG. 12.

the patient lived up to a strict regime. Since cystine stones are soluble in alkalis, we administered large doses of sodium bicarbonate by mouth and irrigated one kidney pelvis with a solution of sodium bicarbonate.

On May 6, 1929, No. 6 and 7 F. catheters were both passed to the right kidney pelvis and left in position. Irrigation was begun through the smaller catheter with sodium bicarbonate solution every ten minutes, the solution draining from the kidney through the larger catheter. After ten hours the catheters stopped draining and were removed. Sixty grains of sodium bicarbonate was given by mouth four times daily. A low cystine diet was also given. On the third day the patient devel-

COMMENTS

The results in these 3 cases show how discouraging the usual treatment of cystine stones is. Surgical removal of the offending stone is merely the beginning of the cure of the patient.

Each of these patients had the appendix removed on account of attacks of right-sided pain. Then each had stones removed from one or both kidneys and promptly reformed larger stones with a resulting decrease in kidney function.

The first attack of renal colic was always on the right side. The most common

symptom was pain in the back with history of recurring attacks of renal colic over a considerable period of time. Hematuria has been present in each at one time or another, and a history of passing small stones in the urine is common. Frequency and urgency of urination is probably the result of the infection which is always present, and probably plays an important rôle in the formation of the stones.

Strangely enough the family history of each has been irrelevant and we have been unable to find cystinuria in any other member of the families except one brother of D. E. Each of the patients has had unusually good health all his life except for the formation of these cystine stones. There has been no venereal history in any of them.

Cytoscopic examinations have shown very little pathology in the bladder. Stones have either passed entirely, or have remained in the kidneys. A kidney containing a stone showed no function at one time, and after removal of this stone, this same kidney later on was doing all the work. Urine cultures have shown definite infection in each case. Blood chemistry examinations have been normal even when both kidneys were embarrassed with large stones. The longest expectancy for relief after surgery alone is one year.

Plain x-ray pictures have shown the stones in all cases eventually. However, in Case III, repeated x-ray and pyelograms failed to reveal the presence of a stone until it had reached considerable size. Even then the stone was first discovered by a filling defect in the pyelogram. Cystine has been variously estimated to contain from 25 to 75 per cent of sulphur. We have prepared an x-ray of a cystine stone, plain starch paste, and starch paste with 5, 15 and 25 per cent sulphur, to show the various densities obtained. (Fig. 12.) It is apparent that any stone containing 25 per cent sulphur should cast a shadow sufficient for diagnosis.

TREATMENT

Patients suffering from cystine calculi must be treated medically as well as

surgically. The preoperative diagnosis and the postoperative care are more important than the mere removal of the stone.

Before considering an operation, the condition of the ureter and kidney must be determined. An obstruction in the ureter or a ptosis of the kidney may be remedied at the time of operation. To expect the kidney to remain free from stones, one must be certain that good kidney drainage is established. If a stricture of the ureter is present it should be dilated. A nephropexy can be done on a ptosed kidney at the time the stones are removed. Chromic catgut should not be used in the kidney.

It has been established that cystine crystals are either dissolved or disintegrated in an alkaline media. Therefore sufficient sodium bicarbonate should be given to render the urine alkaline and keep it alkaline. The urine can easily be tested morning and night by the patient himself. Potassium bicarbonate, ammonium bicarbonate or other alkalies may be used if sodium bicarbonate is not well tolerated. Sixty grains of sodium bicarbonate three times daily is usually well tolerated and sufficient to keep the urine alkaline.

Infection of the kidneys must be combated. Urinary antiseptics which are active in alkaline urine should be given at intervals. Pyridium may be used for this purpose. Dilatation of the ureters and irrigation of the kidney pelvis with an antiseptic solution is of value.

The gastrointestinal tract should be carefully regulated. Salol may be given for one week of each month.

A low cystine diet should be adhered to. Some proteins contain much cystine and others very small amounts. Milk, nuts, beans, peas, bread, eggs, meat and fish contain large amounts of cystine and should never be permitted. Gelatine, cheese all fruits, all vegetables (except peas and beans), butter, cream, jellies and jams, corn bread or corn cereal (sparingly) contain small amounts of cystine, yet sufficient protein to maintain normal metabolism.

CONCLUSIONS

1. Cystine calculi are medical as well as surgical problems.

2. Cystine stones recur so frequently and quickly that all means at our disposal should be used to prevent this. The probability of stones reforming should be impressed on the patient, who must cooperate in every respect.

3. Cystine stones usually cast a shadow in x-ray pictures. Small stones may cast no shadow.

4. Treatment consists of:

(1) Establishing perfect kidney drainage.

(2) Keeping the urine continuously alkaline.

(3) Urinary antiseptics.

(4) Ureteral dilatation and kidney pelvic lavage.

(5) Gastrointestinal antiseptics.

(6) Low cystine diet.

I wish to take this opportunity to thank Dr. Lowsley, Dr. Butterfield, and Dr. Seward Erdman for permitting me to report these cases. I also wish to thank Dr. Frederick B. Henschel for helping prepare this paper and for many helpful suggestions.

CANCER OF THE LIP AND BUCCAL MUCOUS MEMBRANE*

WILLIAM D. JAMES, M.D.

HAMLET, N. C.

PROBABLY no field of malignancy has proved so hard to deal with successfully as that where the growth

dissection being made about $\frac{1}{2}$ inch from the carcinoma, in uninvolved tissue. After this block removal, the edges of the wound

FIG. 1.

FIG. 2.

FIG. 1. Case 1. Epithelioma of lower lip before treatment.

FIG. 2. Case 1. Well after seven years.

involves the lip or the buccal mucous membrane. A cancer of the lip at or within the mucocutaneous junction presents the same conditions which make it as resistant to the various methods of treatment as one located well within the buccal cavity. Both are bathed with saliva, are irritated constantly by the tongue rubbing over them, and cannot be immobilized to any degree on account of the activity of the facial muscles. If the growth is located on the lip without the mucocutaneous junction and does not infiltrate into the substance of the lip deep enough to involve the small labial glands, it will respond readily to radium exposures. When there is involvement of the mucous membrane or where the growth is bathed with saliva, we have found that the condition is very refractory to treatment by means of surgery, x-rays, and radium, or a combination of these methods.

Formerly, it was customary to remove these cancers by surgical operation, the

were sutured with silkworm gut. Carcinomata of the lip and buccal cavity show a tendency to metastasize early; therefore the fat and glands of the submental and submaxillary regions were removed at the time of operation. The precaution to remove the fat and glands of both sides of the neck, even though the carcinoma was distinctly to one side of the median line, was because of the cross lymphatic drainage of this area. According to DaCosta,¹ the submental, submaxillary, and cervical lymphatic glands are usually involved within three months of the beginning of the cancer. He cites a case of his own where they were found to contain carcinoma cells in less than three months after the origin of the carcinoma of the lip. "This involvement cannot be detected by external manipulation in the earliest stages, hence it is not proper to conclude that glandular involvement is absent simply because it cannot be palpated."

cedure is done of inserting the electrode into the normal tissues all around the cancer to the desired depth. Then the electrode is inserted into the cancer itself at short intervals until the whole mass is desiccated out to the line of circular coagulation. The mass of tissue which has been coagulated is then lifted up with tenaculum forceps and removed with a sharp scalpel, the line of incision following the line of coagulation. There is no hemorrhage, as the blood vessels and capillaries have been sealed off by the coagulation process.

A word should be said here in explanation of what the coagulation method is. It must not be confused with any process of cauterizing or burning. At all times the operating electrode is of the same color and remains at room temperature, even though the milliamperage being used is sufficient to devitalize bone or cartilage. As this process is one of direct diathermy, a certain amount of heat will be generated in the tissues to which the operating electrode is applied. This heat generated within the tissues will in turn raise the

tissue, it may be felt as slightly warm. Emphasis is laid upon this fact, for many has a mistaken idea about electrocoagulation treatment of neoplasms, thinking that it is synonymous with cauterization. After the area is coagulated it does not present a blackened or charred appearance. The operating electrode, though a blunt instrument, is pushed readily through normal tissue and leaves a blanched, pearly, coagulated zone for $\frac{1}{4}$ inch upon each side. When the mass of coagulated tissue, including the malignancy, is excised with a sharp knife, there is not a particle of oozing or bleeding along the line of incision. The blood vessels, capillaries and lymphatics are sealed off by the coagulation.

We do not think it advisable to dissect out and remove the fatty tissue and glands of both sides of the neck. The lips, face and buccal cavity have a very abundant lymphatic supply. In view of this fact, it is not wise to remove a few glands and not be sure that all are removed, because the resulting chances of rapid metastasis from the stirring up of cancer cells over a

vast network of lymphatics are too great. The close relation of the lymphatic glands of the submental and submaxillary regions with the lymphatic glands of the superficial and deep cervical lymphatic chains is too likely to cause rapid metastasis if surgical measures are instituted as a safeguard against recurrence of the carcinoma in the neck. The anterior neck area from the inferior maxilla to the clavicles is treated preoperatively and postoperatively with

heavy doses of radium and x-rays, in the hope of destroying the embryonal cells of a microscopic metastatic growth before it is large enough to be palpated. All scalpel surgical procedures in cancer of the lip and cancer of the buccal mucous membrane are contraindicated. The matter of excision of the coagulated area is the removal of devitalized tissue for the comfort of the patient, because it would slough away in a few days.

A CONVENIENT MARKER FOR THYROID INCISIONS*

G. T. TYLER, JR., M.D.

GREENVILLE, S. C.

I HAVE found that bismuth-violet is excellent for marking the line of incision for thyroid operations. The trial necklace in place, the proposed incision is outlined with the dye. When it has dried, painting the field with dilute tincture of iodine or 5 per cent alcoholic solution of picric acid will not obliterate the mark. It remains a black line easily

distinguished. If alcohol alone is used to sterilize the skin, the mark may be obliterated, but not completely so. Though indistinct, enough of the dye may remain to identify the line of incision.

Bismuth-violet is the antiseptic dye recently described by Drs. Barksdale and Wilkinson.¹

MASSIVE DIAPHRAGMATIC HERNIA WITHOUT DIAGNOSTIC SYMPTOMS*

WILLIAM L. KELLER, M.D., COL., M.C., U.S.A.

WASHINGTON, D. C.

UNTIL recent years, diaphragmatic hernia has been more or less of a curiosity and most often found at autopsy. This condition has been more frequently recognized since the advent of the x-ray, and during and since the World War, this type of hernia has been fairly common. It was met with often because of the many abdominal and chest wounds which occurred, leading to a more widespread knowledge of this condition and to a greater opportunity for close study of the traumatic type in particular.

Diaphragmatic hernia has been defined as "the protrusion of any of the abdominal viscera into the thoracic cavity through either a congenital or an acquired opening." Most authorities divide diaphragmatic hernias into the following types, based upon Richards' classification:¹

- I. True hernias:
 - (a) Congenital
 - (b) Acquired
 - (c) Traumatic
 - (d) Non-traumatic.
- II. False hernias:
 - (a) Congenital
 - (b) Acquired.
- III. Eventration of the diaphragm.

The true hernia has a covering consisting of either pleura or peritoneum or both. The congenital type exists from birth, the acquired cases herniate through a natural opening, while the traumatic and non-traumatic do not occur through a natural opening.

The false hernias are without sac or covering and constitutes 90 per cent of the total. Embryonic development of the diaphragm predisposes to formation of both true and false types of diaphragmatic hernias at certain sites. Definite knowledge

is not yet established as to what factors are at work to prevent proper closure of the esophageal, aortic or vena caval openings. It has been claimed that the aortic and vena caval openings are never the seat of hernia because of their anatomical position and protection. The esophageal cases usually herniate posterior to the esophagus. Occasionally herniation occurs through the space of Torrey or the foramen of Bochdalek; more rarely it has occurred after absorption of a large gumma of the diaphragm. The false acquired hernias are all traumatic and usually result from crushing injuries of the abdomen, back, or thorax, from stab wounds or other trauma. Because of these factors the acquired types are usually found in males and the congenital types are found to be equally divided between the two sexes.

Avulsion of the diaphragm from its costal attachment, either complete or incomplete, may be classed under the acquired false hernias. Eventration, properly speaking, is not a hernia at all, but simply a thinning-out of the dome of the diaphragm with the formation of a pouch to receive the extruding viscera.

The greatest number of cases of hernia reported in the literature occurred on the left side for all types because this side offers an easier exit for the abdominal viscera and herniation is facilitated by the negative pressure in the thorax and the positive pressure existing in the abdomen. Hernia is given by the various authors as occurring from six to twelve times² as often on the left side as on the right side. It is reported to be eight times as frequent on this side by Unger and Speiser,³ who also stated that every abdominal viscus except the genital organs and rectum had

Note: Published with permission of the Surgeon General, U. S. Army, who is not responsible for any opinion expressed or conclusions reached herein.

* Submitted for publication July 18, 1929.

been discovered at least once in the thoracic cavity. The organs which are most frequently encountered in the order of their occurrence are: stomach, colon (50 per cent) omentum, intestines and spleen.

The right side is protected by the liver below and the right lung above in addition to the thick crus diaphragmatica. Sezary and his co-workers⁴ report an unusual right-sided hernia where a short loop of the hepatic flexure herniated into the thorax by passing in front of the liver through the ventral portion of the diaphragm due to the absence of fasciculi normally attached to the sternum and costal cartilages. This case was a true hernia exhibiting a sac.

Hedblom⁵ in 1915 made a study of 19 cases of diaphragmatic hernia treated in the Mayo Clinic and 359 found in a comprehensive search of the literature. Two-thirds of the reported cases occurring in civil life were due to penetrating wounds or rupture of the diaphragms by suddenly increased pressure. One-sixth were congenital and one-sixth acquired. In a large percentage, hernia was recognized only after symptoms had been present for many years.

Symptomatology of diaphragmatic hernia varies according to the site of the opening in the diaphragm and the organs or number of organs involved. In the traumatic type there is usually displacement of thoracic viscera by the abdominal organs which have escaped into the thorax. There is commonly dyspnea, cyanosis and disturbed heart action. A tympanitic note may be elicited over the thorax, which may be bulging. Gurgling or sounds of peristalsis may be heard and vomiting and other symptoms of obstruction may be present. Association of hernia of the diaphragm with crushing injuries of chest and abdomen should always be borne in mind. Penetrating wounds of the diaphragm are usually associated with gunshot or stab wounds of abdomen or thorax.

Treatment of diaphragmatic hernia, when any treatment is indicated, is

operative, and, based upon the many reports in literature, the sooner the operation is performed the better the prognosis

FIG. 1. Case 1. Great omentum, coils of intestines and spleen shown high up in chest and densely adherent. Diaphragm was adherent to transverse colon and to omentum.

and this is particularly true of hernias ensuing after stab wounds or gunshot wounds of the thorax and abdomen. The route of approach may be abdominal, thoracic, or combined. The last is particular useful where the hernial opening is large and contains numerous viscera. The mortality over a period of years has been high, varying from 60 per cent for the thoracic approach to 80 per cent for the abdominal. However, a preoperative diagnosis of diaphragmatic hernia was made in a comparatively small number of cases, the operation usually being performed for intestinal obstruction and hence the high mortality

rate. A preliminary cecostomy to relieve the obstruction as suggested by Truesdale⁶ should reduce this mortality somewhat.

wall as has been reported by Bryan⁷ in his case of complete evulsion from the left chest wall.

FIG. 2. Case 1. Diaphragm split anteroposteriorly and curled back and adherent to itself.

FIG. 3. Case 1. Showing how edges of diaphragm were brought together with interrupted sutures of heavy chromic catgut.

The site of constriction in these obstruction cases has usually been found in the transverse colon, even if the stomach and small intestines has also passed through the opening. Phrenicotomy, by diminishing the lung capacity, may be useful in cases where great difficulty is experienced in returning the viscera to the abdomen and repairing the rent in the diaphragm.

The following case demonstrates how easily this condition may be overlooked even when x-ray examination is made. It accents the importance of examining these cases in the prone position. Gastrointestinal symptoms were absent throughout and there were few symptoms referable to the chest. It also illustrates the improbability of incarceration occurring in these large openings and shows the extreme difficulty which may be experienced in suturing the diaphragm to the chest

CASE 1. C. P. G., a soldier, aged nineteen, was admitted to Walter Reed General Hospital, August 10, 1921, complaining of pain in the back when he stood long or walked far. Present illness began March 21, 1921, when he was at work at Gatun, Panama Canal Zone, digging dirt from a bank which caved in, burying him beneath the falling earth. He was admitted to a local hospital with a diagnosis of fracture, simple, second and third lumbar vertebrae, x-ray examination showing a crushing fracture of the bodies of these vertebrae with marked kyphosis.

In addition he had almost complete paralysis of both lower extremities. By June, 1921 there was marked improvement and he then had good use of his legs except for a slight spasticity and weakness. There were no gastrointestinal symptoms.

Physical examination upon admission was essentially negative except for marked kyphosis in the region of the second, third, and fourth

lumbar vertebrae. The lungs were reported negative. A plaster body cast was applied and after one month a brace was substituted.

connecting the two portions. The meal entered the upper part and practically emptied the lower portion when the patient was recumbent.

FIG. 4. Case 1. X-ray examination following operation showing dome of left diaphragm smooth in outline.

Upon return from a three weeks' furlough in October, he was examined with the view to discharge from the service on account of physical disability. It was then found upon examination of the chest that a tympanitic note was obtained on percussion of the left chest from the fourth rib downward anteriorly and in the left axillary region. Over this area borborygmus was marked. Heart sounds were distant but regular, x-ray examination of the chest showed the right lung field clear, and the right diaphragm and costophrenic angle normal. In the left chest from the level of the third rib anteriorly downward the lung field was obscured and no bronchial markings were seen. The diaphragm could not be outlined. In view of possible diaphragmatic hernia, a gastrointestinal series was made. This showed the esophagus normal, the stomach high and apparently in the thoracic cavity extending to the level of the eighth rib anteriorly on the left side. The stomach outline showed a circular constriction at the junction of the lower and middle thirds, the barium passing through a small tunnel

FIG. 5. Case 11. Loop of colon extending above diaphragm to level of second rib.

On standing the lower portion filled. The transverse colon entered the chest cavity and extended to the level of the seventh rib in the axillary line. Fluoroscopic examination showed that the stomach and colon pierced the diaphragm and entered the thorax posteriorly and externally to the apex of the heart.

On January 26, 1922, the patient was operated upon by the thoracic approach. Incision was made in the seventh interspace on the left side and extended from close to the angle of the ribs posteriorly to the anterior axillary line anteriorly. The seventh and eighth ribs were divided at either extremity of the incision and the intercostal muscles cut through and ribs turned up and down. The great omentum and coils of intestines presented which when pushed aside showed what appeared to be a complete absence of the diaphragm and the hand was easily introduced into the abdominal cavity. The spleen was seen high up in the chest to the outer side, densely adherent to the chest wall and to the torn margin of the diaphragm, which was also adherent to the transverse colon and to the omentum. (Fig. 1.) The viscera were dissected

free and easily returned to the abdomen. The diaphragm was split across its fibers anteroposteriorly and was torn away from

rent in the diaphragm. In this case the symptoms present were predominantly referable to the chest.

FIG. 6. Case 11. Large ragged rent in diaphragm which was torn in at least three directions.

its attachment to the chest wall about 1 inch posteriorly and about twice that distance from the anterior wall. The inner side of its anterior attachment was torn away for a distance of $1\frac{1}{2}$ inches on each side of the rent. This formed a quadrilateral-shaped flap which was curled back and adherent to itself. (Fig. 2.) The bands of adherent connective tissue were divided and the edges brought together with interrupted sutures of heavy chromic catgut. (Fig. 3.) The greatest difficulty was experienced in suturing the diaphragm to the chest wall.

The patient made an uneventful recovery and x-ray examinations one month after the operation showed stomach and colon in normal position within the abdomen and no defects or abnormalities demonstrable. The dome of the left diaphragm was smooth in outline but limited in its excursion. (Fig. 4.)

The next case again illustrates how diaphragmatic hernia can be overlooked in spite of x-ray examination and how necessary it is to examine these cases after ingestion of an opaque meal in both the upright and prone positions. This case was of long standing and shows how difficult it may be to return the viscera to the abdomen successfully and to repair the

FIG. 7. Case 11. Stomach, loop of colon, spleen and portion of small intestine protruding into thorax through rent in diaphragm.

CASE 11. A. S., a soldier, aged forty, was admitted to Walter Reed General Hospital, December 2, 1925, complaining of pain in the left shoulder, shortness of breath, especially at night, and cough. He stated that in November, 1918 he was kicked in the left chest by a mule and almost immediately developed a cough which had persisted up to the time of admission. Following the kick he was sick in quarters for one week when he returned to duty which he continued to perform until 1923, when he was admitted to hospital with a diagnosis of left pleurisy with effusion. X-ray examination at this time showed a marked increase in density extending from the fourth interspace to the base on the left side, obliterating all lung markings. There was a dense band, apparently pleural adhesions, extending across the chest at the level of the fourth rib. The heart was displaced to the right.

After five months' observation the patient was transferred to another hospital for the treatment of pulmonary tuberculosis from which he was later again returned to duty. He did special duty as a saddler until the expiration of his enlistment. He re-enlisted

but was unable to do much duty and was sent to Walter Reed General Hospital for treatment. Physical examination at the same time of

seventh interspace extending from anterior to posterior aspect of the chest. The seventh and eight ribs were sectioned to permit easier

FIG. 8. Case 11. On approximating rent in diaphragm, defect remaining was closed by bringing inward from thoracic wall a muscle flap from latissimus dorsi.

admission was essentially negative except for the chest. The heart was not enlarged, sounds were normal, but it was displaced to the right. Examination of the chest showed tactile fremitus diminished over the lateral aspect of the left chest. The percussion note was increased and the breath sounds and spoken voice sounds were greatly diminished over the outer aspect of the left lung. X-ray examination of chest showed marked displacement of the heart to the right. The right lung was negative. The right diaphragm was smooth and the left dome elevated. There were two large gas bubbles in close relation to what appeared to be the inferior surface of the diaphragm. Examination with the opaque meal showed the above shadows to be in the stomach and colon. In the upright position they ascended so that a part of both viscera was above the diaphragm. The funds of the stomach reached to the level of the second rib anteriorly. A long loop of colon appeared above the level of the diaphragm and reached to the level of the second rib. (Fig. 5.) In the prone position the outline of the diaphragm was not definitely shown. The stomach emptied in six hours.

On December 31, 1925 the patient was operated upon through an incision in the

FIG. 9. Case 11. X-ray following operation showing muscle flap in place completely obliterating defect in diaphragm.

access to the cavity. A large rent about 5 inches in diameter was found in the diaphragm. (Fig. 6.) Through this rent protruded the stomach, a loop of colon, spleen and a portion of the small intestines. (Fig. 7.) The stomach and the colon were adherent to the mediastinum. After freeing the stomach and colon these viscera were replaced with difficulty in the abdominal cavity. Attempt was made to repair the rent in the diaphragm. This rent was ragged in outline, the diaphragm being torn in at least three directions and after drawing the edges together there still remained an opening nearly as large as the palm of the hand, which could not be approximated. A portion of the latissimus dorsi was brought inward from the thoracic wall and the defect closed by this muscle flap. (Fig. 8.) Before closing the chest the lungs were inflated by positive pressure. At the completion of the operation it was noted that the intra-abdominal pressure had been markedly increased due to the replacement of the abdominal viscera which had been so long outside their natural cavity. The patient left the operating room in good condition. The day following operation x-ray of the chest

showed the muscle flap in place completely obliterating the defect in the diaphragm. The costophrenic angle was clear. (Fig. 9.) In the afternoon the patient's abdomen became distended and tense. All efforts to move the bowels failed and under local anesthesia an enterostomy was done and a Bonney tube inserted in a loop of ileum. The day after the enterostomy the patient began to manifest symptoms of tetany. The convulsions persisted in spite of every treatment, gradually becoming stronger and of longer duration until the next evening when death ensued. Autopsy showed all sutures intact. There were about 500 c.c. of a bloody exudate in the left pleural cavity and a fibrinous pleurisy of both lungs with some plastic exudate on the left. The upper half of the small intestines were distended and the lower half were empty. A preoperative phrenicotomy would have aided materially in the closure had the magnitude of the condition been suspected.

In conclusion it is desired to stress again a point which has been emphasized many times before and that is that massive diaphragmatic hernia in a large majority of cases is recognized only after it has existed for a long time. Objective and subjective symptoms may be few and there may be little in the history of a given case to suggest the presence of such a condition.

Diaphragmatic hernia will continue to be overlooked unless careful x-ray examination is made including examination by means of the opaque meal with the patient in the upright and prone positions.

These cases show the improbability of incarceration with its attending intestinal obstruction and the difficulty sometimes encountered in repairing the rent in the diaphragm.

The part played by crushing injuries and external violence in causing this type of hernia should always be borne in mind.

TRAUMATIC SPONDYLITIS*

EDGAR D. OPPENHEIMER, M.D.

NEW YORK

FOLLOWING trauma many patients develop symptoms of a back disability equivalent to a spondylitis. In spite of repeated examinations, from the symptoms the patient presents we are unable to make a diagnosis other than spondylitis and by this we mean that there is a sensitiveness of the joints of the back, usually the lumbar spine. His complaints and the way of handling himself correspond to a general spondylitis of a mild inflammatory character and the essential complaints are pains in the back, a weakness or inability to use his back and a spasticity of the spine which acts like a reflex spasm. The pains may not be referred to definite locations; they are usually fairly general and are not diagnostic in themselves. The spasticity is not a fixed condition; it is possible to secure relaxation and motion in recumbency and the weakness as in cases of sprain is not real but simply an inability to use the muscles without causing increased reflex spasm and pain. The roentgen-ray findings are essentially negative showing the degree of bone ossification corresponding to the age, congenital anomalies and unevennesses which we know the patient has had without symptoms.

When the symptoms allow of a more definite diagnosis on an anatomical basis we can improve on our nomenclature. The essential elements of this group, however, do also apply to cases with an interesting anatomical lesion whose diagnosis after all depends upon our fortunate ability to gain concrete evidence of a condition which in itself cannot explain the patient's general condition, such as fracture of a rib or tip of a lateral process. When we speak of this condition as a spondylitis we bring to each other's mind a definite clinical syndrome and the terminology is therefore justified. A true spondyli-

tis it is not. Only very rarely is traumatism alone the cause of an inflammatory reaction in the spine such as we can demonstrate readily following other joint fractures. Slight impactions of vertebral bodies may occur but if the x-rays are not definite we have no right to make a diagnosis of a serious lesion. I say serious mainly because so many of the cases are known to run a prolonged chronic course. All sorts of lesions do occur but when we resort to the term traumatic spondylitis we denote the absence of objective signs leading to a more definite diagnosis. This symptom complex can best be analysed in three factors:

1. The traumatic condition which is equivalent to a back sprain.

2. The inflammatory, which may be said to be present in all of us and which is a reaction of the tissues and largely dependent on our local sensitiveness and preexisting arthritis.

3. Lastly and more important: the psychic; for it is through this that the symptoms of the organic conditions are expressed and amplified. These factors are very hard to separate, are inherent in the patient and give ground for considerable difference of opinion. It is by a clinical study of these cases that we must value relative importance of these elements.

THE TRAUMA

Back sprains are usually induced by indirect violence. Lifting and falling are the most common causes. Torn ligaments and fascia, internal bruising, ecchymosis and edema are the local lesions. When a bone lesion exists we dignify it with a more concrete diagnosis. It is impossible to demonstrate joint separations, such as a theoretical sacroiliac relaxation or tears of other ligaments of the spine. A sprained

* Read before the Section of Orthopedic Surgery, New York Academy of Medicine, May 17, 1929.

back certainly does occur the same as any other joint sprain and may result in a permanent weakness, but it does not adequately account for most of the clinical picture. We must also consider the possibility that we are dealing with a case that turns out to be a "Kummell," post-traumatic vertebral body absorption. In these cases after a fairly brief disability due to the trauma itself a second stage of comparative recovery sets in during which the patient may even go back to work. This is followed after weeks or months by a collapse of vertebral body with a kyphosis and all the secondary symptoms of a spinal fracture, that is, the localized pains and disability. There is an inflammatory reaction. It is this clinical possibility that prevents us ruling out an organic lesion and encouraging our patients with the certainty of its non-existence. If this condition exists in lesser degrees than a frank collapse we have no means of diagnosing it. We cannot make out the post-traumatic inflammatory reaction without x-ray changes as an objective sign.

I have purposely omitted a discussion of the effects of concussion on the central nervous system. Whether the underlying condition is more or less organic does not change the objective.

INFLAMMATORY REACTIONS

Joint and fascial sensitiveness occurs as a fixed condition in many people. Throughout life they have attacks of real pain in and about joints and although apparently not neurotic or hysterical are readily cured of these pains. Their tissues are more sensitive and more easily inflamed. The tissues may be synovial, peri-articular, fascia, bursa, in fact any tissue well supplied with nerves of pain.

Today we are finding more of our arthritics harboring infections and possibly we will come to the conclusion that low-grade infection may be present in our body tissues as in our intestinal canal with non-pathogenic organisms causing no gross changes. After a trauma and a

destruction of the tissue the local reaction changes, the bacteria gain a foothold and an inflammation ensues. If this reaction is present in a very large percentage of all people, I feel we will have to call it physiological. The liability to reaction after trauma is not entirely pathologic.

With age, sclerotic changes may be demonstrated in joints, as in arteries. These productive or sclerotic changes progress silently; there is less elasticity and the tissues are less able to repair after injury. Mild spondylitis deformans is common in people without symptoms. Injury to such a joint would be more liable to cause an inflammatory reaction.

PSYCHIC REACTIONS

The normal psychic reaction of a person to a trauma is that which will occur in 80 per cent of all people. It is in the recovery that the differences between cases will show themselves most. The stronger recover more completely and the psychically weaker continue with their ailment. The stronger face realities and answer the situation. The weaker delay in adapting themselves. The hysterical live under conditions they imagine and that are not existent as with an infantile mind, in this respect having an incomplete mental development, and they do not place true values on facts. We have been in the habit of considering reaction as pathologic or abnormal. The exciting circumstance is abnormal the reaction is normal. Also any reaction which 80 per cent of all people have cannot be considered pathological and cannot be given as an example of an abnormal condition. We must term this functional, that is within the limits of ordinary normal physiological action. The human being is ever ready to believe things that appeal to him and are easy of conception mentally. On test we find our adult brain still functioning in childhood manner, that our rationalizations are not sufficiently separated from our emotions or desire and that we are too prone to live our desires. At each uncomfortable situation we seek

to balance our conceptions to evade the uncomfortable situation at hand while an adult mind would be more ready to allow it to stand as is and be more immune to its unpleasantness. It is typical in these cases that the psychic disturbance caused is to be met with one at that moment less unpleasant. The patient's attention is therefore transferred to explainable pains, aches and suffering and the memory of these linger with more intensity than does the pain. Also the inhibition of activity, giving a greater feeling of insecurity, depresses the patient's power of action and leaves him in a distressed mental state. This acts as a vicious circle as it diminishes his power of recovery.

It is perfectly easy to see why a person who is constitutionally neurasthenic or hysterical will get into difficulty and stay there, but it is wrong to say that the same reaction does not occur in what we must call normal people. After all, clinically it is the heretofore normal people that give us these difficulties while the constitutional inferiors show their natural bend previously and do not seem to present special problems after trauma to the extent we would expect.

In attempting to explain phenomena doctors are very liable to accept any equation which tallies and is logically sound. Unfortunately we have only one method of proof and that is empirical or clinical. Evidently our conception of what should exist in a human being has been leading us into a false explanation. If we are in difficulty in these matters we find ourselves worse off when we attempt an explanation to a layman, be he the patient, a relative or legal aid. A solution or diagnosis is asked in terms which do not exist.

Immediately after trauma it is impossible to go into the patient's psychical condition because the traumatic condition dominates his attention. As the recovery is gradual his ability to exaggerate and amplify increases and we are in a quandary to estimate the remaining physical disability which originally was considerable

and his hysterical element which was previously not discernible. The memory and the fear of what had gone by still holds his attention. An attempt to get along in the face of the previously induced sensitiveness and apprehension focuses his attention on a way out instead of on a way forward.

Without a frequent examination he feels himself neglected and with it his attention is centered. Examination by different men necessarily has a bad effect. If the second man fails to find what the first man did he loses sympathy and confidence but if he finds more the patient has foundation for doubt of the value of his previous treatment, which is still worse. Any small matter such as the exact location of a sensitive spot is enough. Whatever symptoms the patient has must be valued in terms of the three underlying conditions: a sprained back, a sensitive tissue and an intrinsic ability in a human being to modify his conception of his surroundings and being by what we call voluntary attention. Whether this last is organic or not is beside the question. Personally, I believe all thought is organic like a higher compounded reflex and our ability to translate it into a medium termed words induces us to consider it a different entity, which it is not. It seems, however, that we have the ability, within limits, to direct our attention as we see fit. Maybe even here it is not voluntary but simply an expression of an emotion. In this case our rationalization would be fatalistic or predetermined and simply a higher reflex. Such a conception would let us claim this entire symptom complex as of organic origin.

From a practical point of view we know that the major factors in a traumatic spondylitis cannot be dependent solely on the strain of lifting an object the like of which has been done for years. We must conceive our symptom complex as tri-dimensional, in which one dimension dominates but cannot exist alone. As we see these cases, many border on what we would

like to term a neurosis, this would imply that the organic back lesion did not exist. The diagnosis neurosis should not be made on negative findings, it is a real condition. Unfortunately only rarely can we commit ourselves to that effect; usually our opinion must be suspended until we can see what the case is doing and to what extent it can be modified or compensated by effort.

TREATMENT

The treatment of the immediate accident gives us little difficulty. We can always put on a plaster cast or a brace and then let him up. Some prefer keeping the patient flat in bed and then giving no brace, believing that there is a limit to the bed confinement but none to the partial disability; others feel that the sooner the gradual recovery is inaugurated the better for the patient. Physically either method is satisfactory; psychically either may be wrong. Personally I prefer getting him on his feet in a plaster cast because it relieves this doubts and fears, is safest and is a better way of controlling the patient.

After a plaster is no longer necessary the question of physical therapeutics is considered. The easy cases will get well regardless, the difficult cases thrive on attention and even get to enjoy their illness. If we do not do something for them they feel neglected and if we do something for them they do nothing for themselves. I see all too many cases in which physical therapeutics work in the wrong direction. It gives them a crutch to lean on so they do not stand on their feet. Whatever benefit may be derived from the temporary diminution of physical discomfort is negated by the procrastination of effort on the patient's part. Handing patients over to a technician or a masseur makes matters worse. If it is necessary to resort to electric treatments on account of the patient's desire for attention we should use a modality that is not too comfortable and restful but one that is stimulating and painful. I suggest a metal electrode with

a Oudin current. This raises beautiful welts on the patient's back and temporarily relieves him of his own pains. It is like the Pacquelin cautery by which we cured more ailments than we ever diagnosed.

The reasons for the prolonging of these attentions are not valid medically. Giving the mental encouragement needed by the patient to exert himself is a greater strain on the doctor, for which he gets no thanks. A premium is placed on the cultivation of a condition which we are later asked to remove as if it had no basis and did not exist, but which is then deep in the patient's being. After there is cultivated a neurotic condition we refer the patient to a neurologist who then attempts to make a purely neurological case and unwind the thread. This mental treatment can only be done by the physician having the patient in charge from the beginning, and in these cases it must be done by physical means. These cases go to the orthopedist and it is he who is responsible for the eventual outcome. We have no right to make neurotics of them and then ask for their cure, although that is the method now used, particularly on account of the legal and commercial aspects of these cases. We may not be able to relieve these cases of all their aches and pains but we should diminish instead of exaggerate their disabilities. From whom if not from us should these patients get help. If we insist on considering ourselves only bone carpenters we do wrong in holding these cases.

We cannot make the weak strong nor the sensitive insensible but we can do something to diminish their difficulties. I do not know how to make an accurate chronometer out of an Ingersoll watch nor would any one ask it of me, but I do know that I can use an Ingersoll for the same purpose and to a better degree of satisfaction than a perfect timepiece. The same philosophy must be hammered into the patient. They have no right to expect a perfect condition or a return to a previous one, people do not get younger

again. What they must seek is a method of getting along as well as before with what they now have. Therefore treatments in any form must be secondary to function. Nothing succeeds like success, use of the back is of more value in curing the back than any artificial applications or motions.

Gradual return to work by graded work and a gradual increased effort on the patient's part is the only possible and sane solution. Occupational therapy should be work in mild doses and not entertainment with useless occupation. For these cases outdoor occupation, such as work in a garden, is better than sewing. A prize fighter first tries someone his own size whom he can handle before taking on a champion, for a knock-out would shake his confidence in his ability and from this attitude he could not put forward his best efforts. We cannot expect a weak and sensitive patient to do a man's work on his first attempt at return. Too often we see them, after a two or three day try at their old job, quitting completely disheartened. Their next attempt at work will be complicated by fear of failure and their courage to succeed will be crippled. Part time work on part pay is indicated. Social conditions are against us in our attempt at rehabilitation. That is not our fault; they must be changed, we cannot change nature.

When in these cases the dominant lesion appears to be psychic and the remaining physical lesion questionable, the neurologists have accepted these cases as being neuroses. They label them functional, by which they imply the patient is responsible for his mental activities and that it is his will that is accountable for his condition. They throw out a camouflage screen of motive. Nobody exists in this world without motive, everything is explainable that way. Who wants to be weak? Labelling these conditions functional in no way answers the question. We are all candidates for the same physiological process. They were unwilling to consider the milder degree of hysteria and

neurasthenia as pathological. The neurasthenic is essentially weak and tired and lacks ability to exert effort. The hysterical is living an incorrect mental assumption. He should be curable by a correction of his mental attitude or suggestive therapy. The neurologists show examples where simple suggestion effects cures. These are the long-standing cases where the organic lesion, if present, has entirely run its course. A sudden sharp suggestion is dramatic and appealing, its failure immunizes the patient to more attempts. The scientific doubt that exists in the mind of a learned man prevents his assuming the self-confident attitude of a charlatan and making the definite promises the patient desires. In this regard the quack has a great advantage and is bound to have some success. The socialization of medicine will add to the difficulty of handling these cases and improve the field for charlatans. Patients of this mentality and distrust do not lend themselves to a physician who insists that he should govern the patient's actions. The patient, like a child, wants to guide the doctor's hand and does not confide himself to his care. This subject has been treated by the neurologist as if it was purely a mental condition.

Our inability to completely comprehend these cases is no hindrance to our curing them on an empirical basis and I do not think it is a matter of supreme importance as to which element, the organic or the mental, should be emphasized. From a practical point of view these patients need help, we are the only ones who can give it to them and our reward will come, but unfortunately by being fed more unsatisfactory work if we show we can digest it. Then we will be doing something to elevate the status of the medical profession beyond that of a technician.

DISCUSSION

DR. ROBERT E. HUMPHRIES: Dr. Oppenheimer's paper is an important contribution to the study of backache. It is my opinion

that these unsatisfactory cases have some real basis for the continuance of their pains. The patient usually gives a history of having felt something snap in his back either while lifting or when falling. X-ray pictures may be negative as to disease or traumatism, but it is well to remember that disease in its early stages, regardless of its nature, may not show in an x-ray.

We see many cases who have very definite signs of trouble with negative x-ray pictures. If the doctor tells such a patient that he has nothing wrong with him, the patient is likely to assume that the doctor does not know what he is talking about and will consult someone else. After this has continued through many consultations, one doctor telling him he has rheumatism, another that he has arthritis and still another that he has lumbago, etc., he becomes convinced that he has some rare disease of which the doctors know nothing. This condition of affairs is largely due to ourselves, in our efforts to convince the patient that we know more than his last consultant.

There are many factors in an injury that must be considered and I believe the most important is shock. We do not hesitate to do a double osteotomy on a patient, if necessary and yet if that same patient had both legs broken in an injury he had received he would be liable to die of shock, the effect of which is largely intestinal. A man came to the hospital complaining of an injury he had received in one of the nearby factories; in falling he had broken a rib, which had been treated by the doctor at the Industrial Commission. He still complained of pain but was considered a

malingerer. On examination we found a distinct kyphosis at the 8th dorsal vertebra, markedly increased knee jerks and ankle clonus; he was scarcely able to walk. An x-ray showed a wedging of the 8th vertebra. He was admitted to the hospital, operated on, but did not regain control of his limbs. After his discharge from the hospital he was taken to court month after month for a hearing, his paralysis gradually growing worse all the time, when his case was finally settled he was unable to walk. Within two months of the settlement he regained complete control of his legs. I am quite sure that his condition would not have cleared up if a favorable settlement had not been made in his case, because this man was fearful of ever regaining his health again and therefrom becoming a public charge. When this fear was removed he promptly regained his health.

DR. E. D. OPPENHEIMER: The subject is much too large to be covered briefly. There are too many angles to it; these cases come to us months after injury: the objective examination is negative: there is nothing organic on which we can put our fingers. If other opinions are asked, probably eight different men will give eight different opinions. Which is right? In these cases we have various elements that are developed to different degrees and we cannot explain one without considering the others. With time, the traumatic element diminishes and the mental increases. These patients should not see various physicians. It is bad for them: it adds to their doubts, they should be under better control than they are.

THE GAUZE PACK IN THE TREATMENT OF EMPYEMA OF THE PLEURAL CAVITY*

C. A. ROEDER, M.D.

OMAHA, NEBRASKA

IN THE surgical treatment of empyema of the pleural cavity, the so-called open method has regained favor during the past few years. The procedure designated as the closed method is ideal when it accomplishes perfect results, but it too often must be followed by open drainage. One of the principle reasons for the origin of the closed method was the thought that air in an infected pleural cavity was detrimental, mainly through preventing an expansion of the lung. The presence of air in an infected pleural cavity has never been proved to be harmful and the average application of the closed method of drainage rarely prevents the ingress of air. The presence of air is not, apparently, the cause of failure of the closed method; the lack of sufficient drainage must be given primary consideration.

The open method, with or without a rib resection, and the insertion of drainage tubes is usually satisfactory. If the visceral wall of the pleural cavity is not too thick and inelastic, the cavity is generally obliterated in from ten to thirty days. During this time there is profuse drainage of pus, and the opening into the cavity soon becomes just large enough to admit the drains, preventing an inspection of the visceral pleural wall.

The advantages of the draining tube procedure are that it is simple, easily cared for, and causes little distress. The disadvantages are that the drainage is most profuse and prolonged, and the lung "flaps" during respiration, for several days after the operation, producing a distressing increased cardiopulmonary rate. Not infrequently the exudate pockets away from the drainage tube, and the time for removing the tube is always in doubt, resulting often in a prolonged sinus.

A few years ago I began using the gauze pack in the surgical treatment of empyema of the pleural cavity with results so satisfactory that I feel that they should be reported. I have used it only in those cases requiring open drainage and where the lung was not permanently compressed by an organized thickened pleura and intra-pulmonary scar tissue. The advantages of the gauze pack are: (1) it holds the lung steady following the operation, which is most comforting to the patient; (2) it clears the exudate rapidly from the walls of the cavity; (3) it breaks up the numerous small abscesses in the periphery of the lung, which are usually present; (4) it eradicates external purulent drainage almost completely after forty-eight hours; and (5) it brings about an obliteration of the cavity at least as rapidly as any other method. The disadvantages of this method are that the gauze pack must be changed daily by someone experienced, and the first change is more or less distressful without light anesthesia. The wound in the thoracic wall may require dressings for several weeks after the drainage from the pleural cavity has ceased.

About 4 inches of a rib is always resected and the ends covered with surgical wax. As much of the exudate as possible is removed with a Poole sucker through a stab wound into the pleural cavity. The wound is then made about 4 inches long and, in order to facilitate packing, the parietal pleura is attached to the skin by interrupted sutures. The cavity is now open for inspection, and all of the exudate is removed, adhesions are divided and the walls are very gently wiped with gauze. Secondary pockets are widely communicated with the main cavity. With a long

* From the Department of Surgery, University of Nebraska. Submitted for publication November 7, 1929.

curved dressing forceps the entire cavity, starting at its extremity, is uniformly packed with bismuth iodized gauze, which

FIG. 1. Pleural cavity firmly packed with gauze. Note that every portion of infected pleura is in contact with the pack.

type of gauze has proved most satisfactory. This packing must be most painstakingly performed with the gauze fluffed. The first packing braces the lung by holding it in a fixed position, giving the patient a sense of comfort by preventing an increased cardiorespiratory rate. The succeeding packs are less firm and the cavity each day admits less gauze. Wrapping the blade of a broad retractor around the upper edge of the opening allows gauze to enter the cavity with no friction. In six or seven days, further use of the pack is rarely needed. The older the condition, however, the longer it takes to obliterate the cavity, and 10 days of packing may be necessary. Purulent drainage is generally absent after the third day, which is a marked contrast to those cases in which rubber tube drainage is used. In addition, the patients appear more comfortable owing mainly, I think, to the gauze acting as a splint and bracing the lung and mediastinum. The operations can generally be preformed under local anesthesia and the patients are, in most instances, out of

bed and walking on the second or third day. Besides acting as a drain the gauze pack serves a valuable purpose in acting as a splint or brace to the lung as well as a counterirritant to the infected visceral pleura which assists greatly in the eradication of its purulent exudate.

CASE HISTORIES

CASE I. University Hospital No. 28524. Boy, aged five, lobar pneumonia one month before admission. On May 25, 1929 right 9th rib resected and 500 c.c. thick cream-colored pneumococcic pus evacuated. Cavity packed with fluffed gauze which was continued daily. After second packing practically all purulent drainage had disappeared. The temperature was normal on the third day. Six days later cavity was practically closed excepting a small area in the region of the resected rib. Patient was out of bed the second day following the operation and appeared in excellent condition.

CASE II. University Hospital No. 25318. Boy, aged fourteen, had "flu" three weeks previously. On April 28, 1928 right 10th rib resected and 650 c.c. of a thin dirty-brown-colored pneumococcic pus evacuated. Cavity packed with fluffed gauze and patient insisted upon walking back to his bed owing to the solid feeling in his chest. This patient was out of bed on the third day and with a normal temperature. Practically no purulent exudate was visible after the second day. At the end of the ninth day the cavity had disappeared and no more packing was necessary.

CASE III. Wise Memorial Hospital No. 27744. Male, aged fifty, had "flu" one month previously. On January 23, 1929 right 8th rib resected and 1500 c.c. of thick cream-colored pus evacuated. Cavity packed with fluffed gauze which was continued daily. After the third day practically all purulent exudate had disappeared and the temperature dropped to normal on the fifth day. It required ten days of daily packing before the cavity appeared to require no more drainage. The patient was out of bed on the third day and felt quite well. This case is reported because it required the greatest number of gauze packs in my total series of 8 cases.

CASE IV. Wise Memorial Hospital No.

20621. Male, aged fourteen, had "severe cold" three weeks previously. On February 16, 1925 right 8th rib resected and 400 c.c. of a thick dirty-brown-colored pus was evacuated. Cavity packed with fluffed iodoform gauze, and after the second daily packing no external drainage was visible. The temperature dropped to normal on the second day and remained so after the fourth day. In five days no more packing could be admitted and the patient was out of bed and feeling quite well.

CASE V. Wise Memorial Hospital No. 21729. Male, aged nineteen, had pneumonia ending three weeks previously. On October 12, 1925 4 inches of seventh right rib resected and 400 c.c. of a thick yellow pneumococcic pus evacuated. The cavity was packed with iodoform gauze and on the third day no signs of external purulent drainings were visible. The temperature dropped to normal on the sixth day and no further packing was necessary after the eighth day.

APPENDICEAL ABSCESS (WALLED OFF)*

HARRY M. VOORHEES, M.D.

LOS ANGELES, CALIF.

THE subject I am discussing this evening does not consider those cases of appendicitis in which, from a surgeon's standpoint, the earlier appendectomy is performed, the lower our mortality; also we are not concerned, in this brief paper, with the diagnosis, which probably requires more acumen and judgment than the treatment of this condition, to which we are limiting our discussion.

It is my opinion that we see more of these undiagnosed or mistreated conditions than ten years ago, which is very easily explained by the existence of our numerous, so-called medical cults, faith healing, and the sure-cure electrical devices, or what not, now in vogue and given such wide publicity that the unsuspecting public are easily sold.

There are two recognized types of treatment, namely:

1. Surgery with its numerous technics, differing as to the individuality, experience and judgment of the operator.

2. The "starvation treatment," generally known as Ochner's method.

With the latter, I am aware that good results are obtained only in the hands of men who have had years of experience and whose surgical judgment far excels the average. Even in these expert hands, the errors in diagnosis alone usually exceed 2 per cent. As a wrong diagnosis usually results fatally, we have this percentage to add, in determining the true death rate by this method.

In the surgical handling of walled-off appendiceal abscess there are six essential points of technic which I bring to your attention, and if followed by the profession at large, will result, I believe, in lowered mortality and morbidity of our patients, namely:

1. Incision
 - (a) Location and type
2. Exposure of abdominal viscera
3. Treatment of appendix
4. Drainage
 - (a) At operation
 - (b) Postoperative
5. A sutureless wound
6. Secondary appendectomy.

It seems a waste of time to tell surgeons to make their incision over the area, which is either flat on percussion or bulging and visible to the eye, or in which, if this condition does not exist, the abscess and often indurated abdominal wall can be easily palpated. It is a fact, however, that patients are operated on today, with easily localized pathology, in which no attention is given to the location of the incision. As the appendix is normally under McBurney's point, the attack is made in this region, and we see the non-infected portion of the abdomen opened, and the operator proceeds to perform an appendectomy, after breaking through an abscess wall. If this patient survives, the surgeon did not cure him.

1. By the type of incision, I mean a clean-cut, non-dissecting incision. Just the other day, I saw a man's lower abdomen opened in the midline for intra-abdominal pathology. While the approach was being made, the skin and underlying fat was dissected back on both sides, exposing a strip of fascia 4 inches wide, and I thought at first a herniorrhaphy or some form of plastic surgery was in the making. There can be no excuse for exposing more than the minimum amount of abdominal tissue to infectious material from an underlying abscess. Our incision should be clean-cut and direct down to the pathology.

An ideal incision should, theoretically,

*Read before the Los Angeles Surgical Society, February 8, 1929.

be as wide as the abscess; and in thick abdominal walls is of necessity much wider. Rarely are our incisions too long. Have you ever seen your patient on the day following operation, after shrinkage has taken place, and been surprised at the small opening you made?

2. All of us feel a sense of security after operating a badly infected appendix, if in the removal we have seen and handled only the cecum. By making our approach in the proper location, the abdominal contents outside the abscess cavity are never seen. I realize that there exists the occasional case where the pathology is located intra-abdominally, and no contact with the parietal peritoneum, anteriorly or laterally, is made. In these centrally located conditions, often we can defer surgery until an approach can be found, with no intervening intestine, provided no ileus exists to hasten operation.

3. The less we disturb ourselves regarding the appendix, the happier we will be. There very seldom exists, in the condition we are discussing, an abscess where the appendix does not form a part of, and is well incorporated in nature's wall of omentum, cecum, and frequently intestine. Any attempt at removal will only increase our risk of breaking down this wall and, consequently, spread of infection. If the appendix is easily visible, and rarely this occurs, a simple ligature, before removal, with no attempt at inversion or pursestring of cecum, will suffice; and how well you know our fecal fistula's cure.

4. We make the peritoneal approach as wide as possible, consistent with the area in contact with the parietal peritoneum. After the abscess cavity is opened, a thorough aspiration, with removal of all detritus, enteroliths, and sloughing, loose tissue, is advised. The drainage must be so adapted that no back pressure exists to favor any accumulation of pus, distending the cavity, which we wish to collapse. For only by coaptation of the walls can we hope for granulation tissue to form, with subsequent obliteration. Now glass

and hard rubber tubing, with their well-recognized complications, have long been discarded for soft, flexible rubber drains or tissue. The cause of secondary and recurrent abscess is often premature closure of peritoneum at the site of incision, before nature has ample time for obliteration. Therefore, soft tissue drains are used until the rush of serum, following relief of tension, has subsided. Frequent dressings, at six-hour intervals the first and second days and once daily beginning the third or fourth days, following operation; a forceps inserted down to and through the peritoneal level, with gentle divulsion of opening in the peritoneum, will keep the cavity open. If, in this procedure, pus wells up under pressure, either our drains have been removed too soon, or there is obstruction, which should be remedied by mechanical means. Frequent postoperative aspiration with syringe and tubing is not bad practice, and often removes obstructions that are due to sloughing tissue.

Our drains should pass easily into the cavity, with no constriction or pressure from surrounding muscle. If after the incision we find a tortuous tract leading down to our pathology to be drained, our approach has not been direct, and we may expect trouble. There is a general tendency to leave drains in too long. It is mechanically impossible to obtain obliteration of any cavity with a foreign body between granulating walls. If there is a wide opening, with free exit from a cavity, drains are unnecessary and often obstruct, and consequently an accumulation and back pressure are established, with reabsorption and elevation of temperature. We, therefore, remove all drains as early as possible, when wounds are wide open, often on second or third day, and follow their removal with frequent stretching of the peritoneal incision. Gravity and favorable bed posture are important to maintain. Moist dressings are of no benefit if dry gauze is changed frequently, and only favor maceration and skin infections;

vaseline gauze will protect against skin infections.

5. An incision without sutures produces, we find, the most gratifying postoperative abdominal wound. In draining abscesses, there is no benefit derived from passing sutures through an infected field, out into a non-contaminated muscle fascia or skin. All tissue through which they travel is immediately infected, and furthermore, when tied, they obliterate the space, which you want wide open for drainage. Sutures do nothing curative, but are an added menace, favoring extension of infection under the skin, fat, and fascia outside of our incision. If our fascia and muscle approach to an abscess is too wide, and we are afraid of postoperative evisceration, adhesive splints, not on the anterior abdominal wall, but applied from the posterior lumbar region, well back to the spine, fixed anteriorly with tape or safety pins, give far more support than any suppurative stitch applied in the fascia or muscle.

6. Provided the appendix is not removed by ligation at the cecum, a secondary operation for appendectomy is imperative. Schneck at Urban Hospital, Berlin, in his review of 382 cases of surgically treated appendiceal abscess, had an incidence of 15 per cent recurrent appendicitis, which speaks, unquestionably, in favor of secondary appendectomy. A period of two or three months should elapse after drainage ceases, the nature's removal of all latent potential infected tissue, favoring clean secondary operation.

Deuttman accepts the opinion held at the Giessen Clinic, regarding the two-stage operation, and has abandoned the one-stage radical procedure. In 367 cases

treated solely by incision of the abscess, there were only 3 deaths, a mortality of 0.8 per cent of 314, or 86 per cent, of the patients who come to secondary operation, only one died, a mortality of 0.3 per cent. The total mortality was, therefore, 1.09 per cent which is very low compared with the one-stage, which averages 10 per cent or better.

For six months in 1925 and 1926, I was operating on approximately one-fifth of all emergency cases at the Los Angeles General Hospital, and personally operated on 11 cases with a postoperative diagnosis of walled-off appendiceal abscess, the histories of which I have obtained. The shortest time following an acute attack before operation was six days, and the longest, twenty-one. Hospitalization ranged from sixteen to thirty-seven days, with an average of approximately twenty-four and one-half days per patient. In 9 of these cases the appendix was left in, and was removed in 2 cases. In the 9 with the appendix left in, only one shows a record of secondary appendectomy; although all were told the appendix was not removed, and necessity for appendectomy was explained. There were no deaths, and wounds were essentially healed.

· CASE REPORTS ·

CASE REPORTS BY DR. CHAS. MURRAY GRATZ*

NEW YORK

FRACTURE OF THE FEMUR AND INTERNAL CONDYLE OF THE TIBIA

MISS C. F., aged twenty-two, was first seen in consultation with Dr. C. P. Hussey and Dr. F. J. Schwartz on February 7, 1927. The history was that she had been injured in an automobile accident on October 6, 1926, sustaining a fracture of the left femoral shaft at the junction of the middle and upper thirds, and also a fracture of the upper extremity of the left tibia, the line of this fracture extending obliquely from the lateral half of the upper articular surface downward and inward through the cortex of the inner surface just below the condyle. These fractures had been treated from the time of the accident until the time of examination by means of traction apparatus, Thomas splints, and ice tongs. The use of the latter had resulted in suppuration at the point of their application over both condyles of the left femur. There was absolute non-union of the fracture of the femoral shaft. Motion of the knee was limited to 10° , in a position just short of complete extension.

Open reduction was decided upon, and the patient was operated on at the Post-Graduate Hospital February 10, 1928. After anesthesia, she was placed upon the Albee table, with both legs fastened in extreme abduction. Incision was made on the lateral aspect of the thigh, extending 6 in. below and 3 in. above the point of fracture. Muscle tissue was found interposed between the bone ends, which probably accounted for the non-union. With the Albee saw using a twin-blade a 4 in. graft was taken from the lateral aspect of the lower fragment of the femur and a 2 in. graft from the upper fragment, care being taken to have the two fragments in perfect alignment. The graft from the upper portion of the femur was discarded, and the one from the lower fragment was slid across the point

of fracture and held in position by kangaroo tendon after the Albee technic. The wound was then closed in the usual manner, both

FIG. 1.

FIG. 2.

legs being sustained in wide abduction. The points of suppuration over the lower condyles of the left femur were carefully cleaned and iodine applied. Immobilization was obtained by means of a double spica, including the entire left leg and the right as far as the knee. The left knee was kept in extension and the cast was moulded to support the fracture through the upper portion of the tibia. The patient made an uneventful convalescence.

Radiographs taken through the cast on March 9, 1927, showed the bone graft in position and the fragments in perfect alignment. The cast was cut and the portion to the left leg removed on March 30, 1927, the entire cast being removed on April 4, 1927, and radiographs again made (Fig. 3). At this

* Read before the Section of Orthopedic Surgery, New York Academy of Medicine, 1929.

time the wound was found to be in perfect condition, the legs straight, only 10° of motion in the left knee, and the area of suppuration

able to swim and dance without difficulty, and she had discarded all supports, even a cane, since January 1, 1928.

FIG 3.

FIG 4.

over the condyles had improved. Massage was started, and the posterior portion of the cast was left in place until the patient left the hospital, April 23, 1927, with firm union of the fracture of the femur but limitation of motion in the left knee.

The next problem was to restore motion to the left knee. Massage and gentle manipulation was employed with slight improvement until July 25, 1927. At this time it was considered that the femur was sufficiently strong to permit manipulation of the left knee without danger. Accordingly an anesthetic was given and the knee manipulated until it was found that normal motion could be obtained. This was followed by massage, and the patient made an uneventful convalescence.

When seen on September 29, 1928, she was

POTTS' DISEASE TREATED BY MULTIPLEX GRAFT TECHNIC

THE patient, L. B., aged twenty-four, had suffered for many years from an extreme kyphosis of the mid-dorsal region due to tuberculosis, and finally developed a psoas abscess.

The technic used in this case is especially adapted for cases of marked deformity of the spine in which immobilization by tibial grafts of the spinous processes is desired. In many such cases it is not possible to secure a single graft of sufficient width to accommodate itself to the degree of kyphosis.

Four grafts were taken from the tibia, being cut sufficiently thin to permit their adaptation to the extreme kyphosis presented.

These were placed at right angles to the direction of the split spinous processes, the periosteum and medullary sides being alternated, and were firmly fastened in position by kangaroo tendon. The trapezius muscles were lapped over one another in order to prevent any tendency to straining of the grafts; the grafts were also placed one beneath the other from above downward, thus giving the maximum thickness over the point of greatest kyphosis and securing a leverage action, tending to give firm immobilization of the diseased area.

The history was typical of tuberculosis of the dorsal spine; the kyphosis had reached an angle of about 45° , and a psoas abscess had developed and discharged for about six months previous to the operation. An x-ray examination showed destruction of the 5th to the 12th dorsal bodies.

The operation was done on October 26, 1926. On November 21, 1926 a postoperative x-ray was taken, after which the patient was allowed to sit up. The psoas abscess discharged intermittently until November 19, 1927, but has not recurred since that date. No casts or braces were used at any time.

At the time of presentation the patient was free from any discomfort and was able to live a normal life.

DISCUSSION

DR. FRED H. ALBEE: Dr. Gratz is to be congratulated on the results of the technic applied in this case. In such a case with dorsal region when the kyphosis is so markedly angular the spinous processes have separated widely and in as much as the diameter of the spinous process is small, the amount of bone available locally is most inadequate even though it might have inherent active osteogenetic potentiality. This, however, is not the case as we have every evidence the vertebral bone has a lower osteogenetic potentiality, as shown clinically by the frequent absence of repair following both disease and trauma in all portions of the vertebrae. Spies has pointed out that a fissure fraction of the articular process rarely unites and recommends operative fusion. Union of fractional lateral or spinous processes is the exception rather than the rule. The frequency of unsatisfactory repair or even complete failure of repair of a fractional or crusted vertebral body is well known, absorption or recession of bone frequently continuing long after the trauma.

I tested experimentally this relative osteogenesis at Cornell Experimental Laboratories in 1910 and 1911, by taking blocks of bone of equal size from the spinous processes and ulnae of dogs, and incorporated them in various parts of the body of the dog, and I found a marked difference in the growing ability of the different types of bone, the vertebral bone being far below that of ulna bone. In such cases as this above all others, I believe we need additional bone, and bone of a higher osteogenetic potentiality than that of the vertebral bone.

As to the technic, in putting in grafts over a kyphosis as extensive as this, there are only two ways: one by the carpenter's method of bending a board about a rounded corner. He first makes numerous saw cuts most the way through the board on what is to be its concave side. Lateral tension then causes each saw cut to close at the concave surface of the board as it bends. The multiplication of saw cuts allows the bone to bend about a very pronounced kyphosis. In later years I have changed this method, by making the most of the bundle of reed principle and thus make the grafts very thin, cutting the bone from the tibia in thin strips and laying them somewhat as Dr. Gratz has indicated.

DR. LEO MAYER: This is one of the most marked kyphoses we have ever seen at the Post-Graduate Hospital, amounting to almost 180° . Having tried in curves of a lesser grade to put in bone grafts, I realize how difficult it is to get a graft that will really hold. I would like to know from Dr. Albee and Dr. Gratz whether the alternative method of shaping grafts by multiple saw holes would fit a curve of this degree.

DR. ALBEE: I would refer Dr. Mayer to a case in my last book¹ where the kyphosis was very nearly as great as this, with the graft in place, but it is a very much more difficult operation than this, and I would recommend this one.

DR. GEORGE ANAPOL: I had a case of acute kyphosis, I believe a little more acute than the one presented, where I used three pieces of bone, making a bracket, so that the upper graft goes in the upper leg of the angle, the second in the lower leg, the two meeting at the point of kyphosis, and the third or thinner one coming between the two at about 45° .

¹ Albee, F. H. *Orthopedic and Reconstruction Surgery*, Phila., Saunders, 1919.

thus getting the bracket formation. The apex, of course is filled with bone, and thus we have a similar mechanical condition to the one Dr. Gratz has worked out with the curved graft. This case is of twenty-years' duration. Since the graft operation the sinus has healed. That is another method of helping these acute angular conditions.

DR. GRATZ: I was particularly gratified by the end result for we got a very firm fusion, which showed that the pathology had completely cleared up.

As to the operative time, it was forty minutes. I am certain that if any fusion other than by bone graft had been done the patient would not have stood the operation.

TRANSPLANTATION OF THE URETER INTO THE BOWEL*

ROBERT E. KINLOCH, M.D., F.A.C.S., AND LEO S. DREXLER, M.D.

BROOKLYN, N. Y.

ENCOURAGED by the work of Coffey, Peterson, Furniss and others, who have recommended the implantation

FIG. 1.

of the ureter into the large bowel for incurable vesicovaginal fistula, as well as in tuberculous ulcerations of the bladder with a good remaining kidney, we are reporting a case where several attempts at plastic repair were unsuccessful and where employment of this procedure brought relief after years of suffering and a cure of her condition.

T. H., colored, aged forty-seven, was admitted to the Urological Service of the Cumberland Street Hospital with a diagnosis of vesicovaginal fistula. Her chief complaint at the time of admission was an inability to control her urine. She had been married for fourteen years and had never had any children. There was a history of three miscarriages in the early months of pregnancy. The family history was essentially negative, there being no history of tuberculosis in any of her family. She had had whooping cough and measles during childhood and an attack of rheumatic fever at the age of fifteen. There was no history of pulmonary disease. Her trouble began ten years before admission with frequency and burning on urination.

She entered the Johns Hopkins Hospital at that time, where a diagnosis of right tuberculous kidney was made and nephrectomy advised. She refused operation and was discharged.

Five years ago her symptoms became aggravated, she entered Bellevue Hospital on May 29, 1924 and a right nephrectomy was performed. The pathological report confirmed the diagnosis of tuberculous kidney. However, she had very little relief and in addition, three years ago she began to wet herself. She became progressively worse and soon found it impossible to control her urine at all and with this complaint she entered our service on December 26, 1928.

Physical examination revealed a fairly well-nourished individual. Examination of the head and neck was negative; breath sounds were everywhere vesicular in character; no

* Submitted for publication August 15, 1929.

râles heard. The abdomen was soft, no masses were palpable; scar of right nephrectomy noted.

The bladder was filled with methylene blue and the fistula visualized. The fistula was found to be rather large with rigid walls.

On January 8, 1929, under spinal anesthesia, an attempt was made to repair the fistula through the vaginal route. Following this there was no leakage for about ten days. The area appeared well healed and we were about to discharge her when she again began to dribble urine.

On January 30, a second attempt was made to repair the fistula; this time by the suprapubic route. The fistula was visualized, resected and closed. The bladder on inspection showed signs of multiple ulcerations, apparently tuberculous in character. A suprapubic tube was inserted and the wound closed.

In spite of this, leakage through the vagina continued and the patient expressed a desire to have something done which would give her relief. A transplantation of the remaining ureter into the bowel was decided upon and performed on February 26, following the

technic of Coffey. There was little postoperative discomfort. Fairly clear urine was seen to flow continually from the in-dwelling ureteral catheter. There was no abdominal distention.

On March 1, a left parotitis developed which was subsequently incised and drained. On the eighth day postoperative, the ureteral catheter came away. On the eighteenth day postoperative, there was a rise in temperature to 103°F. which lasted for one week and was associated with some tenderness over the left kidney.

From then on, her convalescence was uneventful. She has no difficulty in controlling her urine, voiding every three hours during the day and seldom during the night. Her chemistry one week before her discharge was:

| | | |
|--------------|----|------|
| Blood sugar. | .. | 89.2 |
| Urea. | .. | 23.8 |

| Creatin. | | 1.6 |

Beside x-ray six days postoperative shows ureteral catheter in place draining through rectum.

ARTHRODESIS FOR FLAIL WRIST*

SIGMUND EPSTEIN, M.D.

NEW YORK

THE patient was fifteen years old in January, 1928. He had had infantile paralysis in 1916, and the right arm became paralyzed and useless. He came in with cubitus varus and a flail-like useless arm, with retained power in the biceps and trapezius only. The wrist was characterized by marked supination; his pronators had been put completely out of action by the infantile paralysis, inducing a markedly excessive hyper-supination deformity of the forearm. His hand went back another 45° by curvature of the radius, so that the palm was pointed backward, that is, the thumb pointing toward the center of the body. This produced marked insecurity.

On January 29, 1928, I did a preliminary stretching, putting the hand in pronation in plaster-of-Paris. On March 15, 1928, an arthrodesis was done. The patient now has

a member which he can use for holding objects. Before operation, anything that was put on the palm of the hand fell off; now he can use the hand for grasping objects and bringing himself toward the flexed, grasping hand. He can now catch and pitch, which is a desirable function, and can lift objects with his hand, due to the stabilized wrist.

There is nothing extraordinary about the case, except that there have been very few operations of this sort demonstrated here since Dr. Arthur Steindler was here; but the patient now has a more useful hand than before, partly owing to the fact that the stretching has proved so useful in the preliminary treatment.

The method of arthrodesis was: A dorsal incision, disclosing practically no

* Read before the Section of Orthopedic Surgery, New York Academy of Medicine, May 17, 1929.

useful tendons, was made. The cartilage was simply peeled off the carpal bones wherever we found it by means of a knife; it was soft and easily separated, leaving a mass of pulpy cancellous short bones and bony cancellous medulla of the long bones of the radius and metacarpus. We then impacted these together in as good a position as we could get, which resulted fortunately in the extended position the boy now has. No graft was used.

DISCUSSION

DR. BOORSTEIN: Was anything done to shorten the tendons of the wrist? They must have been quite long on account of the flexed position.

DR. R. E. HUMPHRIES: We have operated on several of these flail arms at the New Jersey Orthopaedic Hospital in Orange and have found that an arthrodesis such as Dr. Epstein describes gives very favorable results in controlling deformity of the hand and also in restoring usefulness. The results are not as uniformly good as an arthrodesis of the foot but a fair percentage of excellent results may be expected.

DR. ARMITAGE WHITMAN: Dr. Humphries spoke of the comparative results in the treatment the upper with the lower extremities. A friend of mine had complete paralysis of the upper extremity. He came to me one day and said: "I have found a miraculous Swede in Boston who has been working on me with massage." I asked him: "What can you do now that you could not do before?" and he moved his thumb over to approximate his

little finger. And when I enquired as to the practical importance of an apparently insignificant movement he replied, "Well, I can now hold a bit of bread in my hand; I could not do that before. Now I can also hold a cigarette." These small improvements are very important and emphasize the great difference in the estimation of results between the upper and the lower extremity. In the lower extremity a muscle to be of functional importance must be practically normal. Whereas in the upper extremity the slightest movement may be of great value.

DR. EPSTEIN, *Closing*: At the first view of these tendons on the wrist one was struck with their excessive tenuity. There was no action to any of the tendons; they were flabby, thin, yellow, did not appear to be of much help in the way of transplantation work with any of them. I might have done some transplantation, but I have much more faith in bone operations than in questionable tendon operations. Dr. Whitman's remarks were very pertinent to this case. The boy regained a fair amount of power in the long flexor of the thumb. He can hold a fairly large object between the first finger and thumb; this has been developed since his operation. He had deformity at the metacarpal phalangeal joint of marked extension, and I was anxious to do an osteotomy across all the metacarpals for the purpose of increasing the flexion, but that is another thing that is improving since the operation; he has opened up a wide range of motion and can do much more with his fingers because the adhesions have been overcome and he has more power in the intrinsic muscles; but the muscles on the back of the wrist offered very little hope for any sort of operative work.

FRACTURE OF LATERAL CONDYLE OF FEMUR ASSOCIATED WITH TEARING OF ANTERIOR CRUCIAL LIGAMENT*

LEWIS CLARK WAGNER, M.D.

NEW YORK

OSTEOCHONDRAL fractures are by no means rare and after a thorough review of the literature one finds a great amount to be written on the subject. This type of fracture associated with ligamentous tear no doubt has been observed on many occasions but no definite report of cases made.

Classification. The etiology is always associated with definite trauma where there have been both external factors and muscular violence. The fracture of the articular surface of the femoral condyle (lateral) is the direct result of the factors, which tend to rupture the anterior crucial ligament. The direct factor in the cases described below was the individual being thrown or falling on the partially flexed knee. This was accompanied by violent rotation and forcible extension of the knee as the patient attempted to reestablish his equilibrium. Stretching of the anterior ligament is imminent after such trauma and if the force is great enough, tearing, or even rupture of the ligament, is certain; while if the cartilage or bone of the joint is of adolescent type there can be an associated osteochondral fracture. A. T. Fisher states this condition can be easily artificially produced in the fetus.

Pathology. When one explores the knee joint so affected there is always a moderate degree of synovial hypertrophy. The torn surface of the anterior crucial ligament and displaced bony fragment (which is usually wedge shaped and measures about 1×1.5 cm.) have acquired an attachment to the synovial membrane. There is a y-shaped tear of the anterior crucial ligament, the uppermost part still attached to the fragment and the lower part in situ. The osteochondral fragment may be

dislodged and find a new attachment on the anterior surface of the lateral femoral condyle. The original site of fracture may

FIG. 1.

be covered completely with new cartilage but a small depression is still noticeable. One finds no necrosis in the dislodged osteochondral fragment but usually a proliferation of bony substance has taken place.

Clinical Classification. This type of fracture is very rare and occurs most frequently in the adolescent age. It has not so far been noted past twenty years of age. Its occurrence has been noticed but five times in the careful study of 4873 knee conditions, extending from the year 1880 to 1929 as taken from the private files of the late Dr. Virgil P. Gibney and myself.

The symptoms are marked by the absence of pain. Every knee injury in a young adolescent should be investigated with respect to a ligamentous tear associated with fracture. The line of fracture sometimes becomes distinct after walking has been started following an injury. The

patients walk with a slight limp and there is also a slight tendency to knock-knee, which is due to a partial rotation and sub-

Treatment. The ideal treatment as soon as the diagnosis is established is surgical. The knee joint is explored through a

FIG. 2.

FIG. 3.

luxation of the knee joint. Extension is always limited and flexion is limited beyond a right angle. One finds no increased lateral mobility.

medial incision and a thorough inspection of the joint is made. The osteochondral fragment is easily removed with a small chisel. The attached part of the anterior

FIG. 4.

FIG. 5.

Diagnosis. The physical signs are quite similar to those of a loose body in the knee joint and a true diagnosis can only be made by roentgen ray.

crucial ligament is excised and removed with the osteochondral fragment, after which the knee is forced into complete extension.

REPORT OF CASES

CASE I. (Dr. Wagner.) Miss M. W., aged fifteen years, was seen March 31, 1924 and

FIG. 6.

gave a history of being thrown from a bicycle and injuring the left knee four weeks previously.

170°. There was no tenderness. Roentgenograms revealed a slightly displaced forward fracture of the external condyle with no callus formation. Arthrotomy was performed on April 8, 1924 and the fragment removed. There was only fibrous union. A part of the anterior crucial ligament which was attached to the fragment was excised. Extension was readily executed without further manipulation. The convalescence was uneventful. Walking began on the tenth day and physiotherapy was given on twentieth day. Examination in March, 1925 showed no deformity and full range of motion.

CASE II. (Dr. Wagner.) Miss A. D., aged nineteen, was seen September 10, 1925, because of deformity of left knee and incomplete extension. She gave a history of falling upon the flexed and adducted knee while dancing the tango. The accident happened in October, 1923. There was some difficulty in getting the knee straight. The family physician applied a splint, which was left on two weeks. Roentgenograms revealed a fracture of the external condyle with slight displacement. Massage was instituted and walking encouraged. Motion slowly returned but there was never complete extension and had become less in the past year. Examination of the knee revealed no fluid or tenderness.

FIG. 7A.

FIG. 7B.

It had been treated with adhesive strapping but full extension did not return. Examination was negative except for the left knee. Flexion was normal but extension was limited at

Extension was limited at 170° and flexion 90°. There was a slight knock-knee. Measurements: R. thigh 16 in. R. knee 13½, 13½, 12 L. thigh 15 in. L. knee 13¼, 13, 11½.

Roentgenograms showed a displaced fracture of the external condyle between the joint surfaces. There is no absorption of the fragment and there seemed to be union to the anterior surface of the femoral cartilage. This fragment is evidently the opposing factor, which prevents extension. Arthrotomy was performed October 1925 and the fragment removed with attached part of anterior crucial ligament. The original site of fracture from which the fragment had been dislodged seemed to be covered with cartilage. The knee was forced into complete extension but not placed in plaster. Walking was begun on the tenth day and physiotherapy at the end of three weeks. Final examination December 1928 shows complete function. Measurements are the same and no pain.

CASE III. (Dr. Gibney.) A boy, twelve years of age, was seen November 14, 1911, with a complaint of limitation of motion and pain in the right knee. Two years previous he had fallen while playing tennis and injured the knee. He was forced to stop playing because of extreme pain and immediate swelling. He was put to bed and treated by means of ice bags. At the end of two weeks he had a fair range of motion and was allowed to walk. The pain soon disappeared and function returned, except for complete extension. Examination was negative except for the right knee. There was a slight enlargement of the knee. Motions were good except extension was limited at 170° and flexion at 95° . There was moderate swelling in the popliteal bursa and under the ligamentum patella. Roentgenograms showed a small fracture of the external condyle and a fragment pushed forward and inward. There seemed to be union in the new position of the displaced fragment. Arthrotomy of the right knee was performed by Dr. Gibney in January 1912 and the fragment removed. Plaster was applied with knee in full extension, which was worn six weeks because of associated synovitis with the original injury. Examination two years later showed no difference in the knees.

CASE IV. (Dr. Gibney.) A man, aged twenty-one, came under observation April,

1914 with a history that five years previous he had injured the right knee alighting from a buggy and was incapacitated for a month. Plaster-of-Paris was employed at the onset and on removal he was encouraged to walk. Motion returned but the knee could never be completely extended and at times after exertion it would become painful. Examination was negative except for the right knee. There was slight atrophy about the right knee and thigh. Extension was limited at 165° . Flexion was limited at a right angle. There was no particular tenderness about the cartilages and the patella was movable. Roentgenograms of the right knee showed an old mal-united fracture of the external condyle of the femur, which had become pushed forward and impinged upon the tibia in extension. Arthrotomy was performed on April 30, 1914 and the fragment removed. The knee was encased in plaster with the knee in full extension. Motion was started at the end of three weeks. At the end of six months there was complete function of the right knee and no pain.

CASE V. (Dr. Gibney.) A young man, eighteen years old, was seen on March 7, 1892 with a complaint of incomplete extension of the left knee. He gave a history of missing his footing while turning a somersault, adducting the leg. He experienced extreme pain and was carried home. The knee became promptly swollen and was treated with ice bag and a posterior splint. Walking was encouraged at the end of a month. Examination nine months after injury showed extension of left knee limited at 150° and flexion at 85° . Measurements were not increased. A diagnosis of incomplete dislocation of the semilunar cartilage or loose body in the joint was made. On March 18, 1892 the knee was manipulated and forced into extreme extension. Plaster was removed at the end of six weeks. There are no further progress notes in the history. I assume in reviewing the records of this case that it was one of *fracture of the external condyle but was not recognized because roentgenograms had not been used prior to 1897 and arthrotomy was not performed in those days except for exceedingly urgent reasons.*

BLADDER DIVERTICULUM COMPLICATED BY CARCINOMA OF CLOACAL ORIGIN*

N. P. RATHBUN, M.D.

BROOKLYN, N. Y.

CARCINOMA occurring in a bladder diverticulum, while not a surgical rarity, is perhaps sufficiently out of the ordinary to warrant the recording of individual cases. The case which I am about to report presented a few factors in connection with the clinical history and pathological findings which merit attention.

The patient was a male, single, salesman, aged forty-eight, first seen on July 21, 1926. He had gonorrhea once in youth. This lasted several weeks; there were no complications and he thought he was cured. At the age of thirty-seven he was operated upon for duodenal ulcer. He made a good recovery and has had no digestive trouble since.

His present trouble began four years ago with a sudden severe pain referred over the sacrum extending through to the hypogastric region. A local physician who was called in found a distended bladder and catheterized him with prompt relief from his pain. Since that time he has been catheterizing himself two or three times daily and has not at any time voided any urine naturally. About one year before he had been examined by another urologist, told that he had a diverticulum and operation advised. Examination disclosed an individual rather underweight and somewhat cachectic in appearance. General physical examination was otherwise essentially negative. The prostate gland as palpated by rectum was slightly enlarged and a feeling of fullness was noticed above it. A soft rubber catheter passed easily into the bladder and 12 oz. of very foul cloudy urine were evacuated. He was advised to go in the hospital for further investigation and probable operation. We did not see him again until June 19, 1928, about two years later. In the meantime he had been keeping himself reasonably comfortable with regular catheterization until two weeks ago, when the urine became bloody. The findings were much the same as at the previous examination and this time 16 oz. of bloody foul urine were evacuated. Hospitalization was again

advised and declined. He reported at irregular intervals for bladder lavage until September 18, 1928, when he finally went to the hospital.

FIG. 1. External appearance of diverticulum.

Cystoscopy on September 22 was rather unsatisfactory because of inability to secure a clean medium and because of very heavy folds in the bladder wall which could not be ironed out with the distending medium. However we noticed what we assumed to be the opening of a diverticulum in the port wall just above the trigone and mesial to the right ureteral orifice. The prostate encroached very slightly on the bladder neck.

A cystogram was made and the radiologist reported as follows: Cystogram shows an irregular bladder. Its under, posterior and upper surfaces on the right side are irregular and it has the appearance of being segmented. If this segmented aspect is due to a diverticulum it is a very large one. It might be due to growth practically dividing the bladder and the irregular appearance of the bladder would suggest tumor either intrinsic or extrinsic. The phenolsulphonephthalein output

*Read before the Section of Genito-Urinary Surgery, New York Academy of Medicine, April 24th, 1929.

showed 20 per cent the first hour, 15 per cent the second hour and 5 per cent the third hour.

The blood chemistry was as follows: urea

It was enormously enlarged and its wall was about $\frac{1}{2}$ inch thick. There was a huge diverticulum almost entirely filling the true

FIG. 2. Diverticular cavity lined with smooth epithelial lining of epidermoid type. In lighter areas wall of diverticulum is infiltrated by carcinoma of epidermoid type.

41.4, creatinin 3.57, sugar 138.8; CO_2 combining power 56.5. The concentration test showed a variation from 1008 to 1015.

pelvis, with its opening on the posterior wall just above the trigone and mesial to the right ureter. Surrounding the orifice there was a

FIG. 3. Epidermoid carcinoma lining diverticular cavity.

FIG. 4. Large glandular structures with numerous goblet cells. Lumen of gland is filled with mucus.

Operation September 28, 1928: Median incision from symphysis to umbilicus. The bladder was exposed and freely mobilized.

papillary growth apparently arising from the cavity of the diverticulum and extending down on the trigone toward the internal

meatus. The bladder wall around the orifice appeared to be moderately infiltrated. At this time there was some doubt as to whether anything short of a total cystectomy would suffice, chiefly because of the proximity of the infiltrating area to the sphincter. We finally decided upon excision and resection, which was done, hugging very close to the ureter orifice and also the internal sphincter. There was some doubt in our mind at the time as to whether we had gotten sufficiently wide of the growth. The usual closure was made around a suprapubic tube and ample extravescical drainage. The operation was prolonged and extremely difficult because of dense adhesions to the diverticulum and the patient left the table in rather profound shock from which he rallied quickly with the usual treatment.

The pathological report was as follows:

Gross. The material consists of two large pieces of thickened bladder wall and a large diverticular pouch 8 cm. long and 6 cm. in diameter. This is shaped like a parabola. It is lined with a smooth gray membrane. The opening of the diverticulum in its fixed state is about 4 cm. in diameter. The margins of the opening are firm and white on section and along one margin of the opening some shaggy tumor-like material projects into the cavity of the diverticulum.

Histological. Sections show the diverticular cavity lined with malignant tumor of epidermoid type and this accounts for the gray color of the internal surface of the pouch. There was also in the wall of the diverticulum and close to the internal surface, clusters of adult intestinal glands. Deeper in the wall there are large loculi of mucus, surrounded in places by epithelium of intestinal type and in others by tumor epithelium of epidermoid type. The microscopic details mentioned would indicate that the diverticulum and new growth originated in some maldevelopment of the cloaca in its formation of the rectum and bladder.

Four weeks postoperative the patient was apparently progressing favorably, except that his suprapubic fistula continued to drain and he would not tolerate an indwelling catheter. He went on in this way for another month, up and about the ward, but voiding only a little urine. At this time he began to fail

and rectal examination disclosed a huge mass in the pelvis, part of which I believe was inflammatory exudation and part a rapid

FIG. 5. Multiple collections of mucus surrounded by epidermoid carcinoma cells.

extension of tumor tissue following an inadequate operation. He died on December 7, 1928. Autopsy was not permitted.

The points of interest are: (1) another case of carcinoma arising in a bladder diverticulum; (2) this patient led an absolute catheter life for six years, with no gross demonstrable obstructive lesion, unless it be the direct presence of the diverticulum itself, and at operation there was noted an enormous hypertrophy of the bladder musculature.

It would appear to me that two factors may have operated: (1) the mechanical obstruction of the diverticulum and (2) some more indirect disturbance of the normal mechanism of urination which interfered with the opening of the sphincter muscle. The third point of interest is the pathological report. This is one of several bladder tumors of apparent cloacal origin which have occurred in our clinic and they are being subjected to a somewhat intensive study and will be reported on later by Dr. Fisher and Dr. Denton of our staff.

ROENTGENOGRAPHIC EXAMINATION OF THE FEMALE PELVIC ORGANS*

USE OF OPAQUE MEDIA FOR INTRAUTERINE INJECTIONS AND FORMATION OF
PNEUMOPERITONEUM FOR GYNECOLOGIC AND OBSTETRIC DIAGNOSIS
(FOURTH COMMUNICATION)

JULIUS JARCHO, M.D., F.A.C.S.

NEW YORK

ROENTGENOLOGIC examination of the female pelvic organs has passed the experimental stage and stood the test of time. Very few gynecologists can afford to be without this diagnostic aid.

INSUFFLATION IN DIAGNOSIS

In 1919, Arthur Stein and W. H. Stewart¹ described their method of pneumoperitoneum for roentgenologic examination of the peritoneal cavity. Theirs was the pioneer work in this method in the United States. For insufflation of the abdominal cavity they² used an ordinary lumbar puncture needle inserted one to three fingerbreadths below the umbilicus in the median line. The gas was insufflated slowly from a rubber bag connected with the tank. Either CO_2 , oxygen, or a mixture of the two gases was used depending on the length of time required for the examination. The amount varied from 2 to 4 liters according to the condition of the anterior abdominal wall.

In their original article Stein and Stewart¹ noted that, in the exaggerated lateral Trendelenburg position, the normal uterus with its ligaments can be demonstrated by pneumoperitoneum; also, cystic ovaries and myomatous tumors of the uterus. In a 1920 article they³ stated that the uterus and its appendages are

shown in even better detail with the patient lying on the abdomen, head downward, on a table tilted at about 15 degrees.

In 1921, Rubin,⁴ continuing his experimental findings of 1919, reported intrauterine insufflation of oxygen to determine the patency of the Fallopian tubes. His instrument included a manometer and flow volumeter for measurement of the quantity, flow and pressure of the gas.⁵ If the tubes are permeable, there is a drop in pressure when the gas passes through the tubes into the peritoneal cavity. If they are not permeable, there is a steady rise in pressure and not more than 200 c.c. of gas should be introduced. This investigator^{6,8} states that the patient should be fluoroscoped in the erect position after tubal insufflation, as this will show a single or a bilateral subphrenic pneumoperitoneum if one or both tubes are patent. In his later work he⁶ has used CO_2 instead of oxygen and has added a kymograph⁹ to his apparatus for the graphic recording of variations in pressure during insufflation.

Peterson¹⁰ in 1921 reported his use of Rubin's method for transuterine insufflation of gas. For roentgenologic examination^{11,12} the patient is placed in the moderate knee-chest position with the table inclined, as for the Trendelenburg

* Submitted for publication January 18, 1930.

position, at an angle of about 20° . If the tubes are permeable as shown by the drop in pressure after the initial rise, about

FIG. 1. Author's apparatus, the pressometer, for introducing air or opaque media into uterus, urinary bladder or kidneys, with a Machlett siphonmeter for perabdominal and peruterine introduction of oxygen or carbon dioxide.

800 to 1000 c.c. of gas are allowed to flow into the peritoneal cavity. If they are not permeable, transabdominal insufflation is used, which is indicated also in acute pelvic disease and if there is purulent and bloody discharge. For transabdominal insufflation puncture is made with a spinal puncture needle just below the navel. The Rubin apparatus is used for the abdominal as well as for the transuterine route. Peterson at first employed oxygen but soon changed to CO_2 .

Sage^{13,14} also has produced pneumoperitoneum by both the transuterine and transabdominal routes for roentgenologic diagnosis in gynecologic conditions. He prefers the transuterine route if the tubes are permeable and believes the method of value because it "gives us definite information about the patency of the genital tract from the cervix to the ovary."

INJECTION OF MEDIA OPAQUE TO ROENTGEN RAYS

More recently the method of utero-

FIG. 2. Roentgenogram after peruterine injection of 900 c.c. of gas, followed by peruterine injection of 5 c.c. of iodized oil. The gas entered at a pressure of 180 mm. and dropped to 140 mm. Shadow of retroflexed fibroid uterus is outlined with six arrows. A. Triangular shadow of uterine cavity. B. Tubal sphincter. Note that sphincters are at beginning of interstitial portion of fallopian tubes and should therefore be called uterine, or still better cornual sphincters. C. Isthmus of tubes. D. Ampullae of tubes. E. Free oil in peritoneal cavity. In one place there is a droplet formation of oil in peritoneal cavity, indicating that there was fluid in tubes. F. Nozzle and volsella on cervix.

FIG. 3. Diagram drawn to illustrate various points in Figure 1.

salpingography by the introduction of various opaque media into the uterus and tubes has been developed, utilizing extensively the iodized oils: lipiodol, iodipin and lipiodine. These media have proved of great value in demonstrating normal

pelvic conditions, obstruction and disease of the tubes, tumors of the uterus and malformations; and in some cases they

They have also designed a new table for the examination.

In cases where intrauterine insufflation

FIG. 4. Roentgenogram after peruterine insufflation of 1400 c.c. CO₂ followed by peruterine injection of 6 c.c. of iodized oil. Shows fibroids involving entire uterus. Neoplasm extends mostly to left, encroaching on cavity of uterus as shown by filling defect in triangular shadow on left side. It also occludes left fallopian tube at cornual end. On right there are fibromata of various densities. Fallopian tube on right side is normal and patent. Small amount of oil entering into peritoneal cavity. Sphincter at proximal end of interstitial portion of this tube is well shown.

FIG. 5. Same patient as in Figure 4. Uterine cavity is emptying itself of oil into peritoneal cavity, where it is widely distributed. Irregularity of tumor is shown well in this plate.

have served as therapeutic measures as well.

In October, 1926, Stein and Arens, who¹⁵ had previously employed pneumoperitoneum only for gynecologic diagnosis^{16,17} described their combined use of pneumoperitoneum and iodized oil injections. This was the first time that such a combination had been reported, although each method had been used separately for some time and proved of value. Carbon dioxide was insufflated by Rubin's method and then 2 c.c. of iodized oil injected. The patient was then placed in the Peterson knee-chest position and stereoroentgenograms were made. Stein and Arens¹⁸⁻²¹ have since perfected their method and have designed a new instrument for the combined intrauterine insufflation and iodized oil instillation, which is self-retaining and facilitates the postural changes necessary for roentgenography.

is contraindicated or where the tubes are not patent, they employ transabdominal insufflation for pneumoperitoneum. Carbon dioxide is used as a rule, except in a selected group of cases in which oxygen is employed. From their results these investigators²¹ conclude that "the maximum information as to the genital status, short of surgical exploration, may be obtained by the combined method of pneumoperitoneum and iodized oil instillation."

Some gynecologists have resorted to both tubal insufflation and iodized oil injections, but not the combined method of pneumoperitoneum and uterosalpingography. Forsdike²² in 1925 reported the use both of insufflation of the tubes to determine patency and of iodized oil injections for radiologic study of the uterus and tubes. He did not, however, resort to tubal insufflation for producing pneumoperitoneum nor did he combine the two methods at one examination, but injected iodized oil one week after the insufflation test was made. He used air for insufflation and measured the pressure and the flow.

Haselhorst,²³ likewise, had recourse both to tubal insufflation and to iodized oil

injection, but did not use these methods in combination. He employed tubal insufflation in cases of uncomplicated steril-

FIG. 6 Roentgenogram of pelvic viscera after insufflation of 1000 c.c. of gas, followed by 4 c.c. of iodized oil. It shows a large ovarian cyst anterior to uterus. Faint outline of fundus of uterus is shown posteriorly to that of cyst. Normal triangular shadow of uterine cavity is shown distinctly. Tubes are well outlined. Free oil is entering peritoneal cavity. (For explanation of letters cf. Fig. 2.)

ity to determine tubal patency, and iodized oil injection when the results of tubal insufflation were negative or uncertain and in conditions other than sterility where roentgenologic study was necessary.

Rubin⁸ made comparative studies of his method in tubal insufflation and iodized oil injection in 66 cases. The findings with the two methods agreed in 60 cases, but there was some discrepancy in the other 6.

SOMETHING NEW IN IMPROVED APPARATUS

Of late, I have combined production of pneumoperitoneum with the injection of iodized oil and find the results most gratifying. I place the patient on a J. Bentley Squier table. The latter had to be somewhat modified in order to make it possible to put the patient in the Peterson posture, which I find indispensable for good results in this work.

In the Peterson partial knee-chest posture, the gas fills out the pelvis and enters all recesses around the pelvic viscera.

FIG. 7. Same as Figure 6 drawn to outline roentgenographic landmarks. (For explanation of letters cf. Fig. 2.)

The intestines gravitate out of the pelvis, facilitating greater clearness.

In my opinion, the apparatus I have designed (the pressometer) for the introduction of air or opaque media is especially well adapted for a combination of the two methods. To produce a pneumoperitoneum it is necessary to inject as much as 800 to 1500 c.c. of gas. It would be very undesirable to inject such large quantities of air into the abdominal cavity on account of its slow absorbability. I therefore attach a siphonmeter to the pressometer, through which the volume of gas can be measured, and introduce oxygen or carbon dioxide.

A "Y" connecting piece unites the oil reservoir, siphonmeter and nozzle leading to the uterus. The two short ends of the "Y" have stopcocks. When gas is introduced the stopcock leading to the siphonmeter is opened and gas enters the nozzle and uterus. When this is closed and the stopcock leading to the oil reservoir opened, the oil is allowed to run into the uterus. The oil is forced ahead by a rubber compressing bulb. The pressure of both gas and oil is recorded on the mercury manometer. The stopcock on the gas line has a side opening through which the gas

can be released, when the manometer registers too high pressure, as happens when the tubes are occluded.

FIG. 8. Large right ovarian cyst outlined with arrows. Smaller cyst on left side was taken as a displaced uterus. Body of uterus was concealed by larger cyst. Roentgenogram showed exact pathologic condition. Oil was allowed to drain off uterine cavity before this plate was taken.

needle is plunged through the abdominal wall into the peritoneal cavity. The oil contrast medium is introduced through

FIG. 9. Same as Figure 8. Drawn to illustrate relative size and relationship of cysts to uterus.

the nozzle into the cervical canal, as before.

For preliminary transuterine pneumoperitoneum, connect adapter 1 to the manometer instead of adapter 2; turn arm of stopcock 4 at right angles to tubing to prevent the flow of oil from the reservoir into the nozzle.

Turn arm of stopcock 3 parallel to the tubing which leads to the siphonmeter. Then open the valve of the gas tank and gas will enter through the nozzle into the uterine cavity.

Stopcock indicated by "3" provides for the instant release of gas pressure by turning the arm parallel to the lateral outlet as illustrated.

To inject oil, detach adapter 1 from the manometer and attach adapter 2. Turn arm of stopcock 3 parallel to the lateral outlet as shown in Figure 1, and turn arm of stopcock 4 parallel to the tubing leading from the oil reservoir.

The instrument is then ready for the injection of iodized oil.

If the tubes are found to be occluded, a lumbar puncture needle is connected to the tubing leading from the siphonmeter, instead of the uterine nozzle, and the

THE AUTHOR'S METHOD

It would be superfluous to give the details of the transuterine introduction of the media as they have been enumerated in the numerous works of Rubin⁴⁻⁹ and also my own articles on uterosalpingography.²⁴⁻²⁶

In transabdominal insufflation, all advise that, if there is a scar in the abdominal wall, the needle should not be introduced through this scar lest a coil of intestine be adherent to it. I have done a perabdominal injection of gas in a woman who had had eight operations, five of them abdominal, without difficulty or untoward effect. Most observers state that no local anesthesia is necessary. I fully agree with them, although in some neurotic patients it is best to inject procain at the point of the introduction of the needle.

For beginners, I should advise the use of oxygen for the creation of the pneumoperitoneum rather than CO_2 . The latter may be absorbed too rapidly and the beginner may be so slow in handling the patient as to lose the valuable information that a larger quantity of gas would give

him. Later, however, when one is sure of one's technique and can speed up the work, CO_2 has greater advantage because its

an example. In this instance the combined method helped to exclude malignancy and saved the patient a ninth operation.

FIG. 10. Left ovarian cyst and right cystic ovary. Roentgenogram of pelvic viscera after insufflation of 1100 c.c. of gas. a. After injection of 4 c.c. of iodized oil, tubes are not filled. b. the occlusion of the tubes, when there is a bloody or purulent discharge, or where there is a suspicion of carcinoma of the corpus uteri. The case cited above of the woman who had had eight operations is

amount of oil to be injected and the number of films to be made depend entirely upon the experience of the physician in making a diagnosis and his desire for more complete records. At the beginning, he is

likely to expose more films than after he has acquired greater skill and experience in their interpretation. It is advisable to make one set of stereoscopic roentgenograms.

The combination of these two methods is indicated only when additional information, not obtainable by either method alone, is desired. When successful it enables the clinician to map out normal and abnormal states of the pelvic viscera. It outlines the inside and outside of the uterus. It often shows the tubes and normal ovaries. Neoplasms of the uterus and adnexa are often plainly visible. It also brings out distinctly the sphincters at the proximal end of the interstitial portion of the Fallopian tubes. This would lead one to call these sphincters uterine; or still better, in order to denote their exact location, cornual sphincters. That the sphincter is part of the uterine structure and is lined by uterine mucous membrane was shown by Römckes' anatomic investigations, as reported by S. N. Bakke²⁷ of Norway.

This method makes the diagnosis more precise. It often enables the surgeon to decide beforehand the best type of operation. It gives him a chance to explain to the patient what is likely to be done for her when operated upon. It enables the patient very often to choose the method of treatment, whether it is to be x-ray or surgery. This has happened in my experience on many occasions in treating women with fibroid tumors and sterility. These patients, when informed that the operation would not help them to become mothers as the uterus would have to be sacrificed, chose irradiation instead of operation for the relief of their condition.

I prefer to keep the patients in the hospital for twenty-four to forty-eight hours, especially those who receive more than 1000 c.c. of gas, as they are likely to have a great deal of shoulder pain and abdominal discomfort.

The roentgenograms, in most instances, are highly instructive, bringing out facts entirely unsuspected. On several occasions

I have found the patient to have bilateral ovarian cysts, while the pelvic examinations made by experienced men suggested only one cyst. This occurrence is shown in some of the accompanying roentgenograms. Such a disclosure was of great moment to me when I had told a patient that she had one cyst and assured her that she would retain her menstrual function and power of reproduction. I had to modify my statement after her roentgenogram disclosed neoplasms of both ovaries.

May I again remind the worker that the strictest asepsis should be maintained? Gentleness of technic will gain the coöperation and confidence of the patient, will facilitate the work and lead to good results and few complications. The physician does not require special skill or great training, only undivided attention to minute detail.

I have, in some cases, attempted to fill the bladder with gas after introducing iodized oil into the uterus but unfortunately did not obtain as gratifying information as did F. C. Steinharter and S. Brown.²⁸ Possibly, I did not give it sufficient trial.

I wish to express my gratitude and appreciation to Dr. A. S. Unger, director of the Department of Radiology in Sydenham Hospital, for his kind help and cooperation in doing this work. Also to Miss Florida Wyble, head technician of Sydenham Hospital, for her untiring assistance.

For the sake of brevity the histories of the patients are not given, as this article deals largely with the roentgenologic findings. Interpretation of the findings in most of these cases was corroborated by the subsequent operations.

CONCLUSIONS

1. The combined method of inducing pneumoperitoneum by insufflation and of uterosalpingography yields valuable diagnostic information in gynecology.
2. The author has introduced a new apparatus (the pressometer), which is

well adapted to the combination of these two methods.

3. In the hands of beginners, oxygen is best used for insufflation, because it is more slowly absorbed and allows ample time for roentgenography. In skilled hands, however, the use of carbon dioxide contributes to the comfort of the patient.

4. Use of the combined methods enables

the clinician to map out normal and abnormal states of the pelvic viscera, outlines the inside and outside of the uterus, brings out the sphincters sharply, shows the fallopian tubes and ovaries, and often makes neoplasms of the uterus and adnexa plainly visible.

5. The procedure should be performed in the hospital under conditions of strict surgical asepsis.

THE ROENTGENOLOGICAL ASPECTS OF EMPYEMA*

RALSTON PATERSON, M.C., M.D., F.R.C.S., D.M.R.E.

TORONTO, CANADA

ROENTGENOLOGIC study is of value in empyema in two ways. The roentgenologist's cooperation is required in dealing with suspected cases, for the diagnosis of the presence, amount and position of fluid in the pleural cavity. His assistance, however, is also required in established cases, to observe the progress of the disease, to determine the effects of surgical procedures, and to elucidate factors preventing resolution. Fluid in the pleural cavity, except in minutest amount, can always be demonstrated by complete roentgenologic examination. The appearances produced are, for the most part, characteristic, especially when effusion is the only lesion. Some difficulty may occur in cases with double lesions, either primary lung disease with secondary empyema, or more rarely, primary empyema with secondary lung or pericardial involvement. X-ray study also permits accurate localization, whether the fluid lies superficially or deeply. This cannot be achieved with any degree of certainty by physical examination; in cases of deeply placed fluid it is impossible. Pleural effusions may exist either as free fluid, or may be loculated by adhesions, and may therefore be discussed under these two main headings.

The effusions associated with cardiac or renal disease, with rheumatic fever, with early malignant disease of the lungs and the uncomplicated effusions occurring in tuberculosis are all simple, non-purulent effusions or transudates, and do not properly come under the heading of empyemata. They produce, however, roentgenologic appearances almost identical with those produced by the free purulent effusions. These include a proportion of the acute pneumococcal exudates, and practically all the acute streptococcal, staphylococcal and influenzal exudates

in the earlier stages. From the point of view of treatment, it is of great importance to distinguish these free effusions, especially the streptococcal type, as it is necessary to wait for localization before instituting any form of radical drainage. Free purulent effusions also occur when the simple effusions of tuberculosis, or of malignant disease, become infected; or when the pleura becomes involved secondarily to chronic pyogenic disease of the lungs, such as abscess or bronchiectasis.

Pyogenic effusions have a natural tendency to limitation by adhesions. Such adhesions may exist from the beginning, especially in association with pneumonia, or may occur subsequently, as the disease develops. This causes the formation of localized collections of pus, so-called encapsulated, loculated or pocketed empyemata. These may occur in any portion of the pleural cavity as peripheral, mediastinal, diaphragmatic or interlobar pockets. Pleural effusions other than pyogenic, do not show this tendency to localization.

It is unnecessary to dwell at length on the purely mechanical details of the roentgenologic technique in the examination of these cases. A brief consideration of the general scheme of the examination of an empyema case is, however, advisable. The first roentgenologic examination in most clinics is usually the routine examination of the chest, taking a postero-anterior stereoscopic pair of films, with the patient sitting or standing. Tube distance should be at least four feet. With a patient who is very ill a "bed chest" roentgenogram, with the film under the patient's back and a short tube distance, will have to suffice although it is not of the same value. Such routine films will show the presence of fluid in any part of the chest, except retrocardiac, or low down

* Read before the staff meeting of The Lockwood Clinic, Toronto, February, 5, 1930.

in the posteroinferior sulcus, and will give an indication as to the line of approach for any further studies.

edge of the chest; that is, to establish definitely a relationship to the parietal pleura. The point on the chest wall to

FIG. 1. Axillary loculated empyema as shown in postero-anterior view, illustrating difficulty of diagnosis from one film only.

FIG. 2. As Fig. 1 but roentgenographed in the left anterior oblique position, showing fluid collection to lie posterolaterally.

Following this a fluoroscopic examination is essential. The patient has to be rotated and examined in all possible positions, sagittal, oblique, lateral, upright, prone, and supine. There are several principles involved,—one is to try to bring the surface of any suspected body of fluid into the line of the rays, as the diagnosis of fluid may depend on the determination of a definite edge. This is illustrated particularly well in Figures 1, and 2, which show an axillary loculated pocket as seen posteroanteriorly, and as seen in an oblique position. In the anterior film the ray is taken through the fluid, and the appearance is in no way characteristic; by rotation, however, the clear line of demarcation between the lesion and the lung is well brought out. The second principle is to determine the point at which the shadow suspected to be fluid, comes most prominently in contact with the apparent

which the rays are then tangent, is the point at which puncture can best be done (Point A in Fig. 2, for instance). Another point is to determine whether any marked change of contour occurs with the patient supine, or prone. If at all possible, the position of the fluid density, as seen in the lateral position, should also be determined, irrespective of which oblique position gives the most prominent views.

The same principles hold for the location of pockets in the interlobar fissures. The main fissure between the upper and lower lobes should be considered as a relatively flat surface, running obliquely downward and forward from the level of the second interspace behind, to the sixth rib in front. In the front view we therefore look obliquely through it. To observe the clear-cut edge of a fluid pocket in this fissure, one has the choice of two good positions. In the direct lateral view one is looking

along the fissure from side to side. Or again, by leaning the patient markedly backward and, if possible, tilting the tube

lesion against the film, is of great value. If the shadow caused by the fluid can be visualized even vaguely in a lateral film,

FIG. 3. Interlobar empyema between middle and lower lobes as seen in the posteroanterior view. Aspiration was done under fluoroscopic control and over 20 c.c. of pus was obtained.

FIG. 4. As Fig. 3 showing lateral view. Old lipiodol from previous per-tracheal lipiodolization is still present.

so that the incidence of the rays is from above and behind the neck down towards the xiphisternum, the fissure is visualized from end to end. In both of these ways a fluid edge can be beautifully demonstrated (Figs. 3, 4 and 5, show a pocket so visualized.) The upper surface of the middle lobe lies horizontally and is therefore quite suitably visualized in the posteroanterior position. Study in the lateral position moreover, shows any shadow from fluid in this fissure to lie anteriorly.

Having determined by such fluoroscopic examination the best positions in which to demonstrate the lesion, the patient is again radiographed. One or two additional films are taken in the positions found most diagnostic; this usually includes one oblique position, and one with the patient prone, or supine. In addition, a direct lateral roentgenogram, with the side of the

one can get quite accurate localization. In this way, by the combination of fluoroscopy and radiography, the expense of using multiple films in many positions is avoided.

The roentgenologic appearances produced by free effusions in the pleural cavity are well-known, and are characteristic. There is a gradual obliteration of the clear lung field by a homogeneous dense shadow, commencing with obliteration of the costophrenic angle (Fig. 6) and extending upwards. As seen in the posteroanterior view, the upper margin of the shadow curves from within, upwards and outwards, with a concavity upwards. In the absence of associated lung lesion, this upper edge may be relatively sharp, but as the fluid accumulates, the line of demarcation between fluid and lung becomes somewhat more hazy, owing to the zone of compressed atelectatic lung immediately overlying it (Fig. 7). Actually, the upper surface of the fluid presents a concavity upwards,

not only from within outwards, but also from front to back, the level being highest behind. There is then formed a bowl-

homogeneous; it completely obliterates the line of the diaphragm; and in an ordinary chest roentgenogram it almost conceals

FIG. 5. As Fig. 3 showing the effect of roentgenographing from above and behind, along the plane of the main fissure.

shaped surface in which lies the compressed, partially atelectatic lower lobe.² This conformation is produced by the combined action of the forces of gravity, of the elastic recoil of the lung tissue, of capillary attraction, and of the limiting effect of the fixed hilus.³ This curve is the characteristic sign of fluid, and is particularly true for the transudates, or the thin purulent fluids. A true primary purulent effusion, however, ordinarily commences as a thin surface layer of fibrinous, non-fluid exudate, which at first shows as a general "veiling" of the lung field and as a narrow double line along the axillary border of the lung field. This has been called lamellar pleurisy, and is especially common in children.³ Later, this may remain a narrow continuation of the shadow of the fluid upwards into the axillary line¹ (Fig. 8). The shadow produced by fluid has three definite characters. The density is quite

FIG. 6. Small pleural effusion (tuberculous etiology) occupying the costophrenic angle.

the rib shadows except at the lateral edge. As the fluid increases in amount, it gradually fills the pleural cavity till the whole lung field is blotted out. When any considerable quantity of fluid is present, especially on the left side,³ the heart and mediastinum are pushed over to the opposite side, the ribs elevated and the interspaces widened (Fig. 9). Where the mediastinum has been fibrosed by previous inflammation, this displacement may not occur.

The effect on the distribution of fluid, of change of posture from standing to lying down, is important. With free fluid such as is found in transudates in the absence of a pneumothorax, the fluid moves slowly and almost imperceptibly into the apex, causing a general darkening of the whole lung field relatively to the other side.¹ With true pyogenic exudates, however, the surface of both the parietal and visceral pleura are coated with thin layers

of fibrinous exudate, which tend to fusion at the edges; for this reason very little alteration in fluid level takes place on lying

is always distinguishable by the deviation of the heart and mediastinum towards the side of the lesion, and by the relative rib

FIG. 7. Extensive free empyema of left pleural cavity following influenza. Over 250 c.c. of pus was aspirated and resolution obtained by closed drainage.

FIG. 8. Extensive free effusion (etiology unknown, but a streptococcal culture was obtained from fluid) with upward extension toward the apex.

down. There is some general increase in level, associated with the altered intrathoracic pressure from the abdominal viscera, but there is essentially no redistribution of the fluid even in the absence of true pocketing. (Stewart, of New York, quotes a case of a patient who was completely inverted without alteration of the fluid contours.)¹

The shadow produced by fluid has to be differentiated from the shadow of the various consolidations of the lung or pleura. Of these, pneumonia occurs most frequently. The consolidation of pneumonia is, however, rather less marked; the line of the diaphragm can usually be made out; there is no characteristic curve; and it can often be shown, by fluoroscopic study, that the lesion lies within the lung tissue. The density in malignancy tends to be more circumscribed, and to lack a defined edge. The density produced by atelectasis

collapse on that side. Thickened pleura, resulting from an old lesion, often suggests fluid, but seldom persists over the whole pleural field and, if of long standing, causes contraction deformity of the thoracic cage of that side. A real difficulty, however, is met with when pneumonia or malignancy co-exist with fluid, and it may be impossible to differentiate the shadows produced by the fluid and by the consolidation respectively.

Loculated effusions may form in relationship to any portion of the surface of the pleura, superficial or deep. Various standard treatises^{1,2,3}, on the subject classify and separately describe these pockets in relation to their different situations. They have, however, certain characteristics in common. The shadows produced by such collections are dense, homogeneous shadows with at least one definitely circumscribed edge which follows normal

anatomical pleural boundaries. As tension develops within these closed pockets, they have a tendency, moreover, where they

always at least one defined border which is related to pleura.

In their book on the roentgenology of

FIG. 9. Large pleural effusion filling the whole pleural cavity, associated with malignancy of the lung; 60 ounces of fluid were aspirated.

FIG. 10. Loculated empyema following pneumonia. Patient developed a bronchial fistula, but complete cure occurred following drainage through the chest wall.
